Application Checklist

Instructions:

1. **Please check each box below, as appropriate; and**
2. **The completed checklist *must* be submitted as the first page of the CON application.**

☒ **Attached is the CON application filing fee in the form of a certified, cashier or business check made out to the "Treasurer State of Connecticut" in the amount of $500.**

For OHCA Use Only:

Docket No.: 12-31748-CON **Check No.:** 1482632
OHCA Verified by: SP **Date:** 2-14-12

☒ **Attached is evidence demonstrating that public notice has been published in a suitable newspaper that relates to the location of the proposal, 3 days in a row, at least 20 days prior to the submission of the CON application to OHCA. (*OHCA requests that the Applicant fax a courtesy copy to OHCA (860) 428-7053, at the time of the publication)***

☒ **Attached is a paginated hard copy of the CON application including a completed affidavit, signed and notarized by the appropriate individuals.**

☒ **Attached are completed Financial Attachments I and II.**

☒ **Submission includes one (1) original and four (4) hard copies with each set placed in 3-ring binders.**

Note: A CON application may be filed with OHCA electronically through email, if the total number of pages submitted is 50 pages or less. In this case, the CON Application must be emailed to ohca@ct.gov.

Important: For CON applications(less than 50 pages) filed electronically through email, the singed affidavit and the check in the amount of $500 must be delivered to OHCA in hardcopy.

☒ **The following have been submitted on a CD**

1. **A scanned copy of each submission in its entirety, including all attachments in Adobe (.pdf) format.**
2. **An electronic copy of the documents in MS Word and MS Excel as appropriate.**

Re: Yale-New Haven Hospital and Greenwich Hospital - Establish and Operate an Elective Angioplasty Program at Greenwich Hospital

Dear Ms. Martone:

Yale-New Haven Hospital (YNHH) and Greenwich Hospital (GH) are pleased to submit an original and four copies of their CON to Establish and Operate an Elective Angioplasty Program.

The proposed program, which will augment primary angioplasty services offered as a satellite of Yale-New Haven Heart and Vascular Center, seeks to ensure undisrupted continuity of care for Greenwich Hospital's cardiac patients who prefer to be treated locally.

A notice to the public regarding the CON application was published in the Greenwich Time pursuant to Section 19a-638 of the Connecticut General Statues is enclosed for your information. Electronic copies of the document in Microsoft Word and Excel as appropriate are enclosed also.

Please forward any correspondence to:

Jean Ahn, System Director
Yale-New Haven Health Planning Office (2 Howe 3)
20 York Street
New Haven, CT 06519

Thank you for your consideration.

Contact Person's Fax Number: 203-688-5013

Contact Person's Email Address: jean.ahn@ynhh.org

Project Town: Greenwich, CT

Project Name: Establish and Operate an Elective Angioplasty Program at Greenwich Hospital

Statute Reference: Section 19a-638, C.G.S.

Estimated Total Capital Expenditure: $0

1. Project Description: Establishment of Cardiac Services

Please provide a narrative detailing the proposal.

Greenwich Hospital and Yale-New Haven Hospital, both members of Yale New Haven Health System, propose to build upon the successful Primary Angioplasty program (PAMI) at Greenwich Hospital, which serves as a satellite of the Yale-New Haven Heart and Vascular Center, and which received permanent approval status from the Office of Health Care Access in July 2008 after completion of a three-year demonstration project. This proposal seeks to add elective angioplasty to the other cardiac services provided at Greenwich Hospital as part of the Yale-New Haven Heart and Vascular Center. The addition of elective angioplasty to a community hospital setting represents a national trend in cardiac services that has occurred over the past several years. Certain interventional cardiac services, including elective angioplasty, are no longer exclusively the province of academic medical centers and large teaching hospitals, but are being appropriately expanded to smaller community hospitals with comparable results. The addition of elective angioplasty to Greenwich Hospital's continuum of high quality cardiac services would be in keeping with similar expansions in numerous other states, and would permit the Hospital to more fully utilize and sustain its high quality infrastructure.

Angioplasty is an interventional procedure performed in the cardiac catheterization laboratory that is used to open blocked or narrowed coronary arteries due to coronary heart disease, thereby improving blood flow to the heart. In most cases, it is performed on an elective basis (and called elective angioplasty), although certain patients require a primary (emergency) angioplasty if they are experiencing a certain type of myocardial infarction. In most cases, a stent is placed in the patient's artery during the procedure in order to reduce the likelihood of future blockage in that artery. Elective angioplasty frequently relieves symptoms of coronary heart disease such as angina (chest pain) and shortness of breath. It is a relatively low-risk procedure that does not require general anesthesia and is one of the most common cardiac procedures.

Elective angioplasty services at Greenwich Hospital will complement cardiac services currently provided at the Hospital and will be a part of the integrated Yale-New Haven Heart & Vascular Center supported administratively and clinically by Yale-New Haven Hospital (YNHH). The clinical and operational infrastructure to provide a high quality full-service cardiac program already exists, and will be enhanced by the ability to offer elective angioplasties. Greenwich Hospital is already performing angioplasty on more acutely ill patients through its primary angioplasty program and the staff and physicians are well prepared to perform elective angioplasty for less acute patients. The proposed Greenwich Hospital program will be included in the existing satellite cardiology program of the Yale-New Haven Heart & Vascular Center, and as it does today with the primary angioplasty program, will follow the YNHH clinical safety and quality protocols, credentialing processes and operational policies and procedures. The Medical Director of the cardiac services program at Greenwich Hospital is appointed by the Yale University School of Medicine (YSM) Department of Cardiology and is a member of the YSM's interventional cardiology faculty. In addition, the privileged medical staff is associated with either YSM Department of Cardiology, members of which currently practice at Greenwich Hospital as part of the existing primary angioplasty program or are members

of the Greenwich Hospital medical staff with privileges in performing angioplasties. All associated physicians will utilize the lab in accordance with pre-established clinical protocols and quality standards.

2. **Clear Public Need**

   a. Explain why there is a clear public need for the proposal. Provide evidence that demonstrates this need.

   Approved Docket Number (DN) 08-30148-MDF demonstrated clear public need for emergency angioplasty services at Greenwich Hospital. The current proposal expands upon DN 08-30148-MDF to demonstrate that the same population, from which the Hospital's primary angioplasty patients originate, also have a clear need for access to their provider of choice for high quality elective angioplasty services.

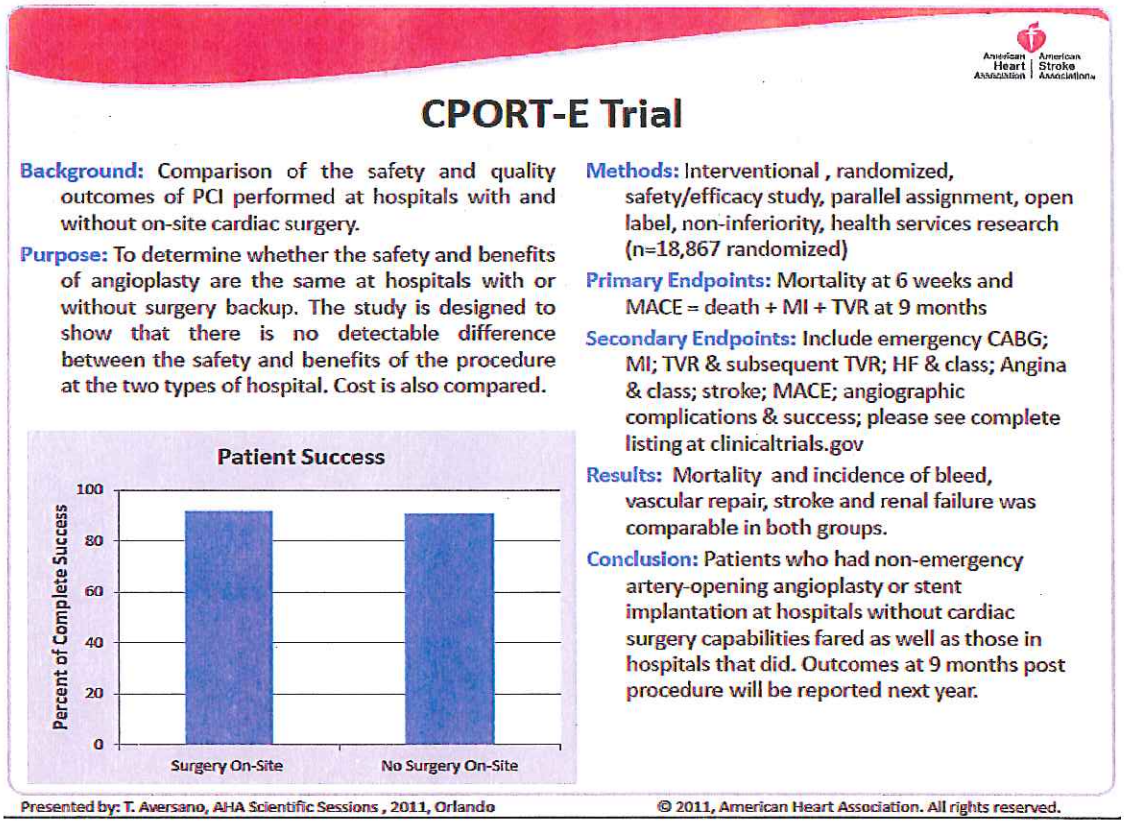
   Clear public need for the proposal is supported by the following three key factors:
   - **Local access to elective angioplasty care at Greenwich Hospital is needed and appropriate:**
   - **Greenwich Hospital must address the cost-effectiveness of angioplasty services; and**
   - **The proposed program will improve the quality of care of elective angioplasty services provided to Greenwich Hospital service area patients.**

   These factors will be described in more detail below.

   <u>Local access to elective angioplasty care at Greenwich Hospital is needed and appropriate</u> as supported by the following three key factors:
   - **Recent clinical guidelines and studies demonstrate the safety and efficacy of elective angioplasty programs without cardiac surgery back-up;**
   - **National and local trends that demonstrate improved access to elective angioplasty; and**
   - **The historical lack of access for elective angioplasty for patients who seek care at Greenwich Hospital.**

   Recent Clinical Guidelines & Studies Demonstrate the Safety and Efficacy of Elective Angioplasty without Cardiac Surgery Back-Up
   The most recent American College of Cardiology/American Heart Association/ Society for Cardiac Angiography and Intervention (ACC/AHA/SCAI) PCI guidelines released on November 7, 2011 represent a significant change in the recommendation level regarding elective angioplasty in hospitals without cardiac surgery programs. The new guidelines assign a class IIB recommendation, which means the benefit is greater than or equal to the risk, for elective angioplasty without cardiac surgery back-up.

Recent studies and publications indicate that standalone elective angioplasty can be safely performed with positive outcomes. The first major study, assessing outcomes of patients undergoing angioplasty at centers with and without surgical back-up, found comparable results at both types of facilities. Preliminary results from the CPORT-E trial led by Dr. Thomas Aversano at Johns Hopkins University were released in mid-November 2011. In this large multi-center study, nearly 14,000 patients were randomly assigned to have elective angioplasty at a hospital with onsite surgical capability, and approximately 4,500 patients were randomly assigned to have elective angioplasty at a hospital without surgical backup. The death rate after six weeks was the same for each group, and neither group of patients was more likely to need emergency cardiac surgery. A summary slide of study results presented in November 2011 at an American Heart Association conference is shown below.



An American Heart Association (AHA) news release summarizing the CPORT-E study's findings, included as Attachment I, stated that "Patients who had non-emergency artery-opening angioplasty or stent implantation at experienced hospitals without on-site heart surgery capabilities fared no worse than those in surgery-equipped hospitals" and also noted the following:

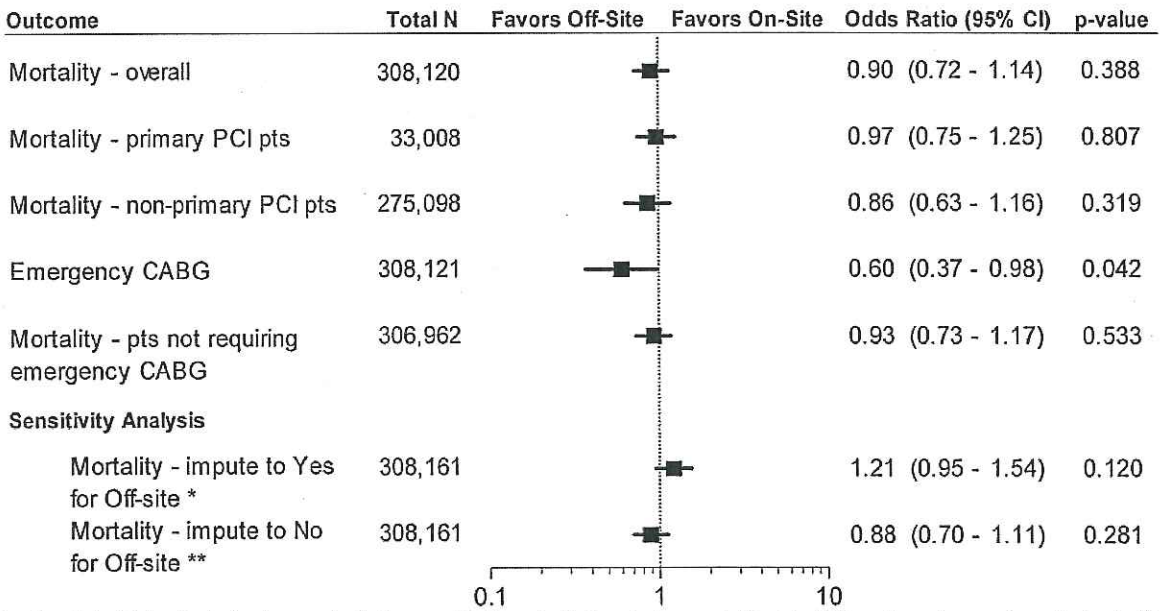
- **Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without heart surgery capabilities fared as well as those in hospitals that did; and**
- **Both groups of patients had less than a 1 percent death rate.**

Interestingly, before results from the CPORT-E study were available, some states (such as New Jersey) that had hospitals participating in the study legislated that these hospitals that had started elective angioplasty programs on the study protocol, could continue their elective angioplasty programs even though the protocol has completed enrollment.

In a separate article, Param Puneet Singh, MD, et al (2011), published '*Outcomes of Nonemergent Percutaneous Coronary Intervention With and Without Onsite Surgical Backup: a Meta Analysis.*' The meta-analysis suggests that there is no difference in outcome with regard to risk of nonfatal myocardial infarction, need for emergency coronary artery bypass grafting, and the risk of death in patients undergoing elective angioplasty in hospitals with and without on-site cardiac surgery backup (see Attachment II).

The National Cardiovascular Data Registry (NCDR, 2009) evaluated the national experience for angioplasty without surgery onsite. The NCDR studied programs that already perform these procedures. Data from 60 hospitals and approximately 8,700 patients who had angioplasty at centers without on-site cardiac surgery ("offsite centers") were compared to 405 hospitals and approximately 300,000 patients at centers with cardiac surgery on-site ("onsite centers"). One notable finding was that after risk adjustment there were no mortality differences between off- and on-site facilities among total angioplasty patients, primary angioplasty patients, non-primary angioplasty patients, or patients who did not require emergency surgery (see chart below). In fact, there were higher risk-adjusted odds of emergency surgery in on-site angioplasty centers.

Risk-Adjusted Analysis of Outcomes



Odds ratio plot of risk-adjusted outcomes, including sensitivity analysis for missing mortality data. Odds ratio: outcomes for patients at off-site (vs. on-site) facilities, adjusting for within site correlations and potential confounding variables. *Worst case scenario: all patients with missing mortality data were considered to have died. **Best case scenario: all patients with missing mortality data were considered as alive. CABG _ coronary artery bypass graft surgery; CI = confidence interval; PCI = percutaneous coronary intervention; pts = patients.

Source: Kutcher, M, et.al, Percutaneous Coronary Interventions in Facilities Without Cardiac Surgery On Site: A Report from the National Cardiovascular Data Registry (NCDR), Journal of the American College of Cardiology, Volume 54, No. 1, June 30, 2009, pgs. 16 - 24

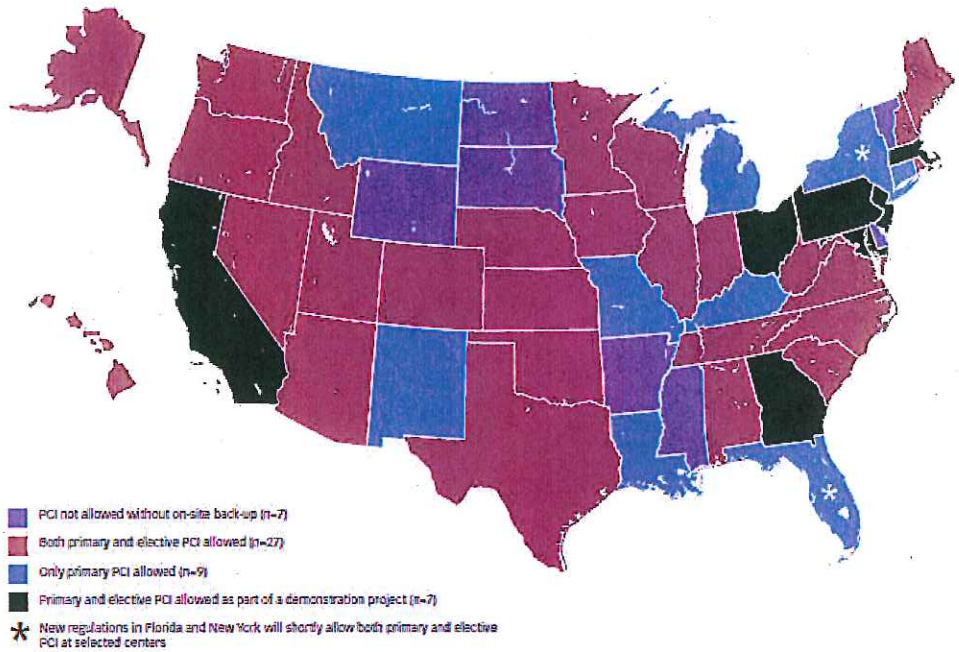
Despite lower annual angioplasty procedural volumes and more patients presenting with myocardial infarction (MI) subsets, off-site angioplasty facilities reporting to the NCDR Cath PCI Registry had similar rates of procedural success, morbidity, emergency surgery, and risk-adjusted mortality when compared with on-site angioplasty centers. Another potentially important observation is that on-site surgery did not necessarily confer an advantage for the rare patient that did require emergent surgery. In cases that required emergency surgery, off-site angioplasty centers had similar observed procedure success, morbidity, emergency cardiac surgery rates and mortality. (See Attachment III)

National and Local Trends Demonstrate Improved Access to Elective Angioplasty

In the past several years, the interventional cardiology field has experienced a significant expansion of services. Health Care Advisory Board research shows that as of 2009, 34 states allowed elective angioplasty to be performed without surgical backup, including New York, Pennsylvania, New Hampshire and Maine; seven of the 34 states allowed it as part of a demonstration project. In New York, ten hospitals have been granted approval to provide elective angioplasty without on-site cardiac surgery, including White Plains Hospital in White Plains. In January 2011, California enacted a six site "pilot" program for elective angioplasty without on-site cardiac surgery.

The map below, by the Health Care Advisory Board, shows the states that allow percutaneous coronary intervention without onsite cardiac surgical back-up as of 2009.

Figure 1: Status of Percutaneous Coronary Intervention without On-site Cardiac Surgical Back-up in the US



There are now only seven states (Arkansas, Delaware, Mississippi, North Dakota, South Dakota, Vermont, and Wyoming) where neither primary nor elective percutaneous coronary intervention (PCI) is allowed without on-site surgery. Legislation is pending in California to allow a carefully monitored demonstration project of elective PCI without on-site back-up. Primary PCI without on-site surgery is allowed in Washington, but not elective PCI. However, Washington has a liberal definition of emergency PCI such that patients with acute coronary syndromes and non-ST segment elevation myocardial infarction who have stabilized are allowed to undergo PCI at facilities without on-site surgery. Florida and New York both have rule changes pending to allow both primary and elective PCI at selected facilities without on-site surgery. Modified from Dehmer et al., 2007.[10]

Source: Dehmer, Gregory, J., Percutaneous Coronary Intervention without On-site Surgical Back-up, US Cardiology, 2009, Vol. 6 (1), pages 69-74

Since this map was published in 2009, both New York and Florida have allowed elective angioplasty without onsite surgical backup, as the footnote indicates.

Significantly, of the 34 states that allow standalone elective angioplasty, 28 require Certificate of Need regulatory approval, including New York. The majority of states permit both primary and elective angioplasty. Based on the new ACC/AHA/SCAI guidelines, the CPORT-E trial results and other recently published studies, one would expect elective angioplasty without cardiac surgery back-up to continue to expand.

An additional indication of the reduced level of risk of elective angioplasty and the routine nature of the procedure is the trend towards performing the procedure on an outpatient basis. This practice occurs throughout the country, including Connecticut. The percentage of inpatient angioplasty in Connecticut has declined each year from 98.9% in FY 2008 to 89.6% in the latest CHIME data from FY 2011.

The Historical Lack of Access for Elective Angioplasty for Patients who Seek Care at Greenwich Hospital

Since Fiscal Year 2008, 272 patients came to Greenwich Hospital and needed elective angioplasty but could not access this service. Limits placed on access to this routine cardiac procedure required these patients to be transferred to another facility, in some cases outside Connecticut. Due to existing physician referral patterns, the majority of these 246 patients were transferred to Yale-New Haven Hospital, as shown in the table below. An additional 26 patients were discharged and referred for elective angioplasty at a future time.

Number of Patients Discharged Directly from GH to Another Institution for Elective Angioplasty

Fiscal Year	Yale-New Haven Hospital	Westchester Medical Center	Cornell	Columbia	Stamford	West Haven VA	Total Transfers	Number of Patients Discharged Home and Referred for Elective Angioplasty in the Future	Total Cases
2008	44	1	0	0	0	0	45	9	54
2009	71	0	1	1	1	0	74	5	79
2010	51	0	2	0	1	0	54	10	64
2011	53	0	2	1	0	1	57	2	59

*Number of transfers to another institution between October 1, 2011 and December 31, 2011

Source: Greenwich Hospital Cardiology Department

Therefore, in total since FY 2008, 272 patients sought invasive cardiac care at Greenwich Hospital but could not access the necessary services in their local community. As a result of this lack of access, there are several adverse patient implications. First, the lack of access to elective angioplasty at Greenwich Hospital means that these patients received two invasive procedures instead of one since their diagnostic cardiac catheterization was performed at Greenwich Hospital and a

subsequent angioplasty was performed at a second facility. This results in increased risk for infection, delays in receiving the care required, and additional costs for a second procedure. Second, patients who were medically fragile, were subjected to transport to another facility. Third, transferring patients to another facility creates an unnecessary stressful and uncomfortable situation for patients and family. Fourth, transferring to another facility is an increased stress for the patients and their families with regard to transportation. For some, in Greenwich Hospital's greater service area, transportation outside the service area is problematic.

Greenwich Hospital Must Address the Cost-Effectiveness of Angioplasty Services
As previously described, service area residents who obtain a cardiac catheterization at Greenwich Hospital and require a subsequent angioplasty procedure must undergo two invasive procedures at two institutions. This practice increases the costs of care to patients and payers and ultimately to the health care system as a whole. Patients have to incur the additional out of pocket costs for the second procedure as well as additional transportation costs for themselves and possibly also family members. With patients receiving two procedures at two separate institutions, payers have increased expenses for the care provided to patients. Eliminating a second invasive cardiac procedure would improve the cost-effectiveness of angioplasty services for service area residents.

Primary angioplasty is a critically needed, lifesaving service that the Hospital provides to the community. Greenwich Hospital made significant investments in its primary angioplasty program in order to provide a necessary service to its service area, however, the costs of operating such a small program impede the Hospital's efforts to provide cost-effective care. An agreement is in place with the Yale School of Medicine to provide 24/7 coverage at the Hospital so that a highly skilled interventional cardiologist is always either on-site or in close proximity should a patient be in need of primary angioplasty. Greenwich Hospital is responsible for paying $1.78 million per year to the Yale School of Medicine to provide physician staffing for the primary angioplasty program. While this physician model is an essential component of the primary angioplasty program, it results in significant staffing costs to cover approximately 40 primary angioplasty cases treated at the Hospital each year. Allowing these same physicians to also perform elective angioplasty at Greenwich Hospital would be a cost-effective and efficient approach and would reduce the costs per case from the current arrangement. Since the current physician staffing covers 24/7, no additional physician expense is required to add elective angioplasty. Therefore this proposal represents a cost-effective solution to angioplasty services in Greenwich Hospital's service area.

The Proposed Program will Improve the Quality of Care of Elective Angioplasty Services Provided to Greenwich Hospital Service Area Patients
Greenwich Hospital's partnership with clinical faculty from the Yale School of Medicine and its membership in the Yale New Haven Health System will improve the quality of elective angioplasty services to Greenwich Hospital service area residents. As previously noted, service area residents who present to or desire elective angioplasty treatment at Greenwich Hospital are subjected to transfer to another Connecticut hospital and a second invasive procedure or may receive their care at a

New York hospital. The transfer process, additional procedures, and transportation out-of-state do not constitute high quality service or a positive patient experience. The term elective angioplasty is misleading as patients may have unstable, acute coronary symptoms, yet must be called elective since they do not meet the criteria for emergency angioplasty for STEMI. The proposed program will allow service area residents to remain in the local community and obtain elective angioplasty services from some of the nation's leading interventional cardiologists.

Greenwich Hospital's partnership with the clinical faculty from the Yale School of Medicine (YSM) has been a key factor in the success of its primary angioplasty program. The program is staffed by some of the nation's leading interventional cardiologists, who maintain a busy clinical practice, and many of whom perform angioplasty procedures far in excess of the minimum national standards each year. These clinicians are familiar with the Hospital's medical staff and operations. They also bring with them the procedures, clinical protocols and safety standards that are in place at Yale-New Haven Heart and Vascular Center, one of the Northeast's and nation's leading programs. In addition, the interventional cardiologists from YSM currently perform elective angioplasty procedures both at Yale-New Haven Hospital and at the West Haven VA, and are highly skilled in performing the procedure, with demonstrated outcomes that attest to their excellent quality. In fact, these same physicians are providing care to the majority of patients who currently must be transferred from Greenwich Hospital to Yale New Haven Hospital to receive elective angioplasty. Providing elective angioplasty at Greenwich Hospital will allow patients to receive the same high quality care from the same physicians without having to incur the stress of transfers and second procedures.

Greenwich Hospital has been a member of Yale New Haven Health System (YNHHS) for over twelve years. As Yale New Haven Health System has evolved, it has expanded the degree of clinical integration among its corporate members (Bridgeport Hospital, Greenwich Hospital, Yale-New Haven Hospital, and Northeast Medical Group). This clinical integration, which brings significant benefits, including consistent approaches towards clinical quality and safety practices, staffing and training, information systems, knowledge sharing and best practices, is expected to continue. Quality and outcomes will be predictable across YNHHS sites because identical care management and clinical protocols will be followed.

In addition, YNHHS is in the process of implementing the Epic common electronic medical record. This will have a major impact on YNHHS' ability to better coordinate care and services as well as easily implement and monitor best practice policies and procedures among its members, as there will be a shared medical record among all three hospitals and its clinicians. There will be a seamless flow of information within YNHHS and other providers/settings including community physicians. Providers at one site will be able to access information on a patient's visit to a different System hospital. For example, patients that are treated at both Greenwich Hospital and Yale-New Haven Hospital will share a common medical record, allowing clinicians at both sites to have 24/7 access to the most up-to-date clinical information on patients. Such integration would benefit the small number of angioplasty patients that may have to be transferred to YNHH but were also treated at Greenwich Hospital. The

implementation of Epic and the corresponding changes in System-wide processes will also facilitate the easy capture and analysis of data to support performance improvement, outcomes management, public reporting and transparency. Epic will help ensure that regulations and organizational policies and procedures regarding security, privacy and compliance are met. This will enable the Yale-New Haven Heart and Vascular Center to continue to monitor and develop all appropriate standards, protocols, policies, procedures and quality assessments which will be followed by Greenwich Hospital in providing angioplasty services to patients.

Conclusion of Public Need

Based on all of the above factors, the proposed elective angioplasty program at Greenwich Hospital, as a satellite of the Yale-New Haven Heart and Vascular Center, will be an appropriate, cost-effective, high quality program that is consistent with clinical guidelines, recent research and the approach currently being followed in many other states and at many other hospitals. Greenwich Hospital is well-prepared to embark on this project given the existing and proposed infrastructure and the program's success in treating more acutely ill patients with primary angioplasty. The program would be part of the Yale-New Haven Heart and Vascular Center, therefore it would comply with its rigorous standards and requirements, and provide patients with the ability to receive elective angioplasty locally at Greenwich Hospital, where they can benefit from high quality care and continuity, and avoid the complications and stress of transfer.

b. Provide the following regarding the proposal's location:

i. The rationale for choosing the proposed service location;

Greenwich Hospital is a progressive institution offering a wide range of medical, surgical, diagnostic and preventive programs with outstanding results. The Hospital currently provides diagnostic cardiac services including echocardiography, nuclear cardiac imaging, stress testing, cardiac CT angiography, and diagnostic cardiac catheterization. In addition, Greenwich Hospital offers interventional cardiac services to provide primary angioplasty for acute myocardial infarction (MI) patients pursuant to the Hospitals' authorization to provide primary angioplasty service under OHCA CON approval (DN 08-30148-MDF). The Hospital also has a cardiac rehabilitation program with inpatient and outpatient components for post-hospital follow-up care. A detailed list of services is below:

Ambulatory BP monitor	Arterial Doppler (PVR)
Cardiac Rehabilitation	Diagnostic Cardiac Catheterization
EKG Stress tests	Electrical Cardioversions
Peripheral angiography/intervention	Event Loop Recorder Implant
Electrophysiology Study	Holter monitor (24 and 48 hour)
Fetal Echocardiograms	Intravascular Ultrasound of Coronary/ Fractional Flow Reserve
Implantable Cardiac Defibrillator	Percutaneous Coronary Intervention in the event of an MI Alert
Nuclear Stress Tests	Permanent/Temporary Pacemakers
Pericardiocentesis	Trans-esophageal Echocardiograms (with bubbles)
Pharmacological Stress Echocardiograms (Dobutamine)	Trans-esophageal Echocardiograms (without bubbles)
Trans-thoracic Echocardiograms	Stress Echocardiograms

Greenwich Hospital is a logical location for the proposed elective angioplasty program for a multitude of reasons. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital. The Greenwich Hospital cardiac services program, which offers high quality diagnostic cardiac catheterization and primary angioplasty, is already a satellite under the medical direction of the Yale-New Haven Heart and Vascular Center, and employs a YSM medical director as well as YSM medical staff available 24 hours per day, 7 days per week. The Hospital is a longstanding member of Yale New Haven Health System, which will allow it to benefit from continued System-wide clinical integration, collaboration and sharing of best practices.

Patients prefer to be treated locally, close to their residence and family members. For patients in the Greenwich Hospital service area, the option to receive elective angioplasty care at their local hospital, namely Greenwich Hospital, is not available to them. Referring physicians prefer to send a patient in need of interventional cardiology to a facility that can perform both diagnostic cardiac catheterization and elective angioplasty to avoid the need for the patient to be transferred and be re-catheterized if an angioplasty is required. As a result, these patients often bypass Greenwich Hospital entirely although the Hospital is fully equipped to provide services and is an excellent local option for patients.

The lack of elective angioplasty at Greenwich Hospital results in disruptive care for patients. Under the current arrangement, Greenwich Hospital patients have to be transferred to other hospitals for elective angioplasty procedures even though experienced YSM interventional cardiologists and catheterization lab support staff are onsite and available 24 hours every day to provide the needed care at Greenwich Hospital. The vast majority of patients are transferred to Yale-New Haven Hospital, where they are treated by the same physicians from whom they would have received the same care at Greenwich Hospital if Greenwich Hospital was approved to provide elective angioplasty.

In light of these considerations, as well as the previously mentioned trends in many states to allow elective angioplasty without on-site surgery, Greenwich Hospital is an appropriate location for the proposed program.

ii. The service area towns and the basis for their selection;

The primary and secondary service area towns represent those communities which comprise 85% of Greenwich Hospital's inpatient volume. They include:

Connecticut Towns
Darien, Greenwich, New Canaan, Norwalk, Stamford, Weston, Westport and Wilton.

New York Towns
Armonk, Bedford, Bedford Hills, Harrison, Hartsdale, Katonah, Larchmont, Mamaroneck, Mount Kisco, Mount Vernon, New Rochelle, Port Chester, Pound Ridge, Purchase, Rye, Scarsdale, South Salem, West Harrison and White Plains.

The Hospital and its physicians treat many patients with heart disease who live in these service area towns and the proposed elective angioplasty program would serve to provide better access to, and coordination of, cardiac care.

iii. The population to be served, including specific evidence such as incidence, prevalence, or other demographic data that demonstrates need;

Incidence of Cardiovascular Disease
Major cardiovascular disease was the leading cause of death in Connecticut according to Department of Public Health Crude and Age-Adjusted Mortality Rate data for 2006-2008. According to the Connecticut Department of Public Health most recently published *Connecticut Resident Hospitalizations, 2009* report, diseases of the circulatory system totaled 58,853 and diseases of the heart totaled more than 40,000 discharges. There were more than 6,300 discharges for acute myocardial infarction (AMI). As shown in the Table H-5 below, diseases of the heart were the leading causes of hospitalizations for all ages combined, as well as for ages 65 and older in 2009.

Table H-5
CONNECTICUT RESIDENT HOSPITALIZATIONS, 2009
Leading Causes of Hospitalization (Numbers of Hospitalizations) by Age and Sex[a]

Sex	Rank	Age group (Years)						
		0-4	5-14	15-24	25-44	45-64	65+	All ages
Both sexes	1	Respiratory (3,053)	Mental (1,890)	Mental (4,741)	Mental (10,308)	Digestive (12,592)	Heart (27,430)	Heart (40,484)
	2	Injury/Poisoning (619)	Respiratory (1,433)	Injury/Poisoning (2,265)	Digestive (7,437)	Heart (10,902)	Respiratory (19,692)	Digestive (38,952)
	3	Endocrine[c] (503)	Digestive (1,082)	Digestive (2,244)	Injury/Poisoning (4,948)	Mental (10,649)	Digestive (15,138)	Respiratory (36,804)
	4	Digestive (459)	Injury/Poisoning (809)	Respiratory (982)	Genitourinary (3,284)	Musculoskeletal (9,630)	Injury/Poisoning (13,634)	Injury/Poisoning (30,873)
	5	Infectious (372)	Anemias/Blood (326)	Endocrine[c] (631)	Respiratory (2,964)	Respiratory (8,680)	Genitourinary (10,684)	Mental (30,160)
	6	Nervous (354)	Endocrine[c] (315)	Genitourinary (622)	Musculoskeletal (2,945)	Injury/Poisoning (8,598)	Musculoskeletal (10,660)	Musculoskeletal (23,905)
	7	Skin (290)	Nervous (311)	Anemias/Blood (586)	Endocrine[c] (2,894)	Neoplasms[b] (7,928)	Neoplasms[b] (8,371)	Genitourinary (20,495)
	8	Genitourinary (286)	Musculoskeletal (236)	Infectious (469)	Neoplasms[b] (2,483)	Genitourinary (5,401)	Infectious (8,246)	Neoplasms[b] (19,212)
	9	Anemias/Blood (208)	Genitourinary (218)	Nervous (421)	Heart (1,883)	Endocrine[c] (5,002)	Cerebrovascular (6,865)	Endocrine[c] (15,222)
	10	Neoplasms[b] (85)	Skin (211)	Musculoskeletal (391)	Infectious (1,456)	Infectious (3,566)	Endocrine[c] (5,877)	Infectious (14,312)

http://www.ct.gov/dph/cwp/view.asp?a=3132&q=397512&dphNav=|46941|&dphNav_GID=1601

[a] See Appendix and Table H-1 for corresponding diagnostic groups by ICD-9 CM codes.

[b] Includes both benign and malignant neoplasms.

[c] Endocrine, nutritional, metabolic, and immunologic disorders, including diabetes mellitus and volume depletion (dehydration).

According to the Connecticut Department of Public Health Office of Health Care Access' report 'The Burden of Cardiovascular Disease in Connecticut 2010 Surveillance Report' Executive Summary (included as Attachment IV):

- **Cardiovascular diseases (CVDs) are a great public health concern. CVD account for about one-third of all Connecticut resident deaths. Coronary Heart Disease (CHD), cerebrovascular disease (stroke) and heart failure (HF) are the main types, accounting for 48%, 15% and 8% respectively of all CVD deaths.**
- **Cardiovascular disease accounted for about 33% (9,351) of all Connecticut resident deaths in 2008, as shown in the table below.**

Connecticut Resident Deaths, 2008

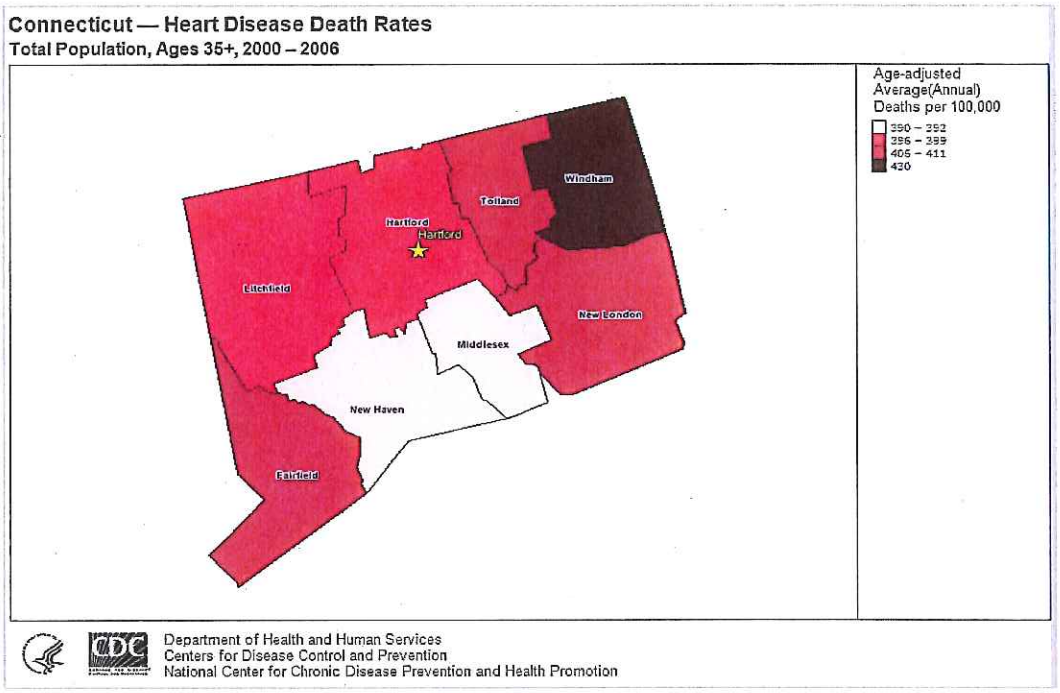
Cause of Death	Number of Deaths	Percent of Deaths
All Causes	28,749	100%
Cardiovascular Disease	9,351	33%
Cancer	6,765	24%
Chronic Liver Respiratory Disease	1,494	5%
Unintentional Injury	1,362	5%
Alzheimer's Disease	831	3%
Pneumonia and Influenza	688	2%
Diabetes	618	2%

Source: Connecticut Department of Public Health Office of Health Care Access; The Burden of Cardiovascular Disease in Connecticut 2010 Surveillance Report, March 2011

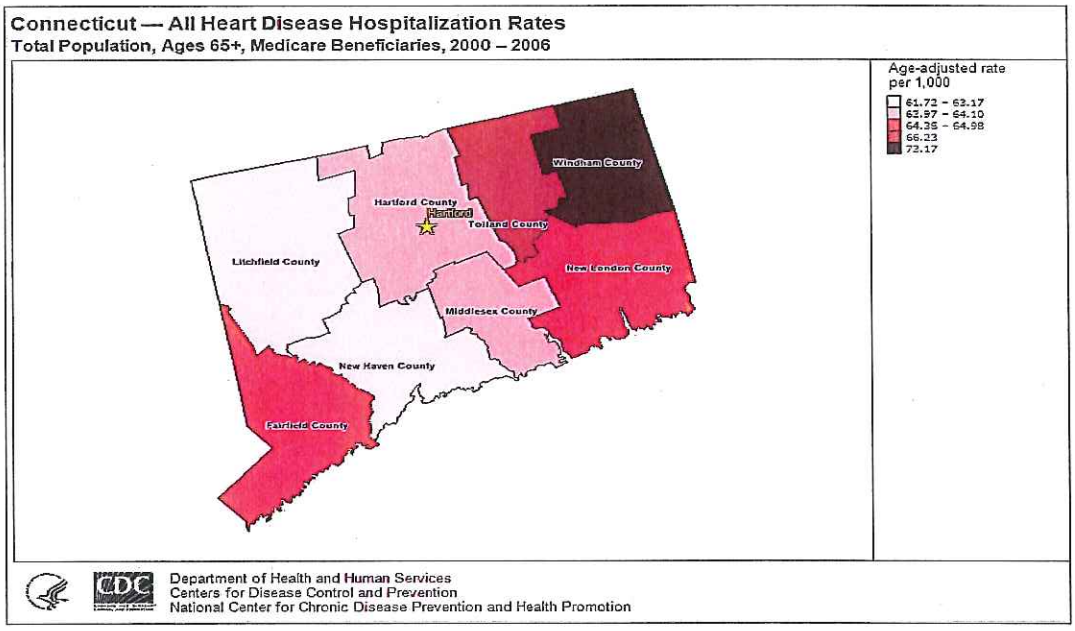
- **About $2.2 billion was billed for CVD hospitalizations in Connecticut in 2008. Approximately 34% of CVD charges are for CHD, 12% for stroke and 12% for HF. CVD also incurs enormous indirect costs.**
- **About 18% of all hospital discharges in Connecticut are due to CVD. Approximately 26% of CVD hospitalizations are due to CHD, 12% to stroke and 18% to HF (2008 data).**

The following maps show the heart disease death rate in Connecticut by county for 2000 – 2006. Fairfield County's heart disease death rate was higher than the rates in New Haven, Middlesex, Hartford and Litchfield Counties. Between 2000 and 2006, Fairfield County had the third highest 65+ heart disease hospitalization rate per 1,000 age-adjusted and spatially smoothed in Connecticut.

Heart Disease Death Rates Map



Heart Disease Hospitalization Rates Map



Service Area Demographics

The following table shows population projections for Greenwich Hospital's Connecticut and New York service area towns. The total service area will consist of over 370,000 people in Connecticut and 440,000 people in New York, of whom approximately 43% are over age 45. Because of Greenwich Hospital's location on the border of Connecticut and New York, it attracts a significant number of New York residents, who constitute a sizable proportion of the Hospital's patient population.

The proportion of Greenwich Hospital's service area patients who are over age 45 and the patients over age 65 are projected to increase between 2011 and 2016, as shown in the population table below. Both the risk and rate of heart disease increase with age, as does the corresponding need for interventional cardiology services.

Population Projections
Greenwich Hospital Service Area

Area & Age Cohort Service Area	2000	2011	2016	% Change 2000 - 2011	% Change 2011 - 2016
0-44	486,078	463,790	454,100	-4.6%	-2.1%
45-54	110,947	131,685	123,671	18.7%	-6.1%
55-64	75,351	101,043	115,399	34.1%	14.2%
65-74	56,212	60,212	72,416	7.1%	20.3%
75-84	37,209	37,304	37,086	0.3%	-0.6%
85+	14,641	18,174	19,883	24.1%	9.4%
Total	780,438	812,208	822,555	4.1%	1.3%
Ages 45+	294,360	348,418	368,455		
Ages 65+	108,062	115,690	129,385		
% 45+	37.7%	42.9%	44.8%		
% 65+	13.8%	14.2%	15.7%		

Source: Claritas

iv. How and where the proposed patient population is currently being served;

Patients from the Greenwich Hospital service area that require elective angioplasty currently go to another hospital in either Connecticut or New York to receive these services. This includes patients who receive a diagnostic cardiac catheterization at Greenwich Hospital and who subsequently require elective angioplasty as well as Greenwich Hospital primary angioplasty patients who have coronary artery disease in other vessels and require a subsequent elective angioplasty. The vast majority of these patients are transferred to Yale-New Haven Hospital and some are treated at White Plains Hospital, Columbia, Cornell and Westchester Medical Center.

Some physicians who currently utilize Greenwich Hospital services to provide care to their patients are often reluctant to direct their patients to the Greenwich Hospital cardiac catheterization lab if there is a clinical suspicion that the patient may require

angioplasty. Currently Greenwich Hospital can only address the culprit lesion for patients in need of emergency angioplasty.

As a satellite of a leading academic medical center's nationally recognized cardiac program, the Greenwich Hospital elective angioplasty program would extend the quality, safety and leading clinical advances of the Yale-New Haven Heart and Vascular Center to its patients and community. The proposed program will adhere to the same rigorous clinical, operator and institutional criteria and monitoring as the YNHH program. Consequently, the program will assure high quality outcomes, care continuity, state-of-the-art, easily accessible and high quality care.

v. All existing providers (**name, address, services provided**) of the proposed service in the towns listed above and in nearby towns;

Stamford Hospital, located at 30 Shelburne Road, Stamford CT 06904 and White Plains Hospital, located at 41 E. Post Road, White Plains, New York 10601 offer elective angioplasty in the service area.

vi. Describe existing referral patterns in the area to be served by the proposal; and

Patients are referred to Greenwich Hospital's cardiology program by their internist or cardiologist. Current referral patterns are with cardiologists within the service area and on the medical staff of Greenwich Hospital. Currently, the cardiologists (including interventional cardiologists) on the medical staff at Greenwich Hospital have practices located in Greenwich, CT (55%), Westchester County, NY (13%) and Stamford, CT (11%). The YSM physicians practicing at the Greenwich Hospital location are included in the Greenwich, CT statistics above.

vii. The effect of the proposal on existing providers, explaining how current referral patterns will be affected by the proposal.

The vast majority of patients who must be transferred from Greenwich Hospital to another hospital for elective angioplasty are sent to Yale-New Haven Hospital. Therefore, a significant proportion of the Greenwich Hospital proposed program volume will represent cases that would previously have been transferred to Yale-New Haven Hospital. This reduction in volume at Yale-New Haven Hospital has been agreed to by clinical and administrative leadership and will not negatively impact Yale-New Haven Hospital's cardiac services.

Recent discussions with the Hospital's current physician referral sources indicate that they support the provision of elective angioplasty at Greenwich Hospital, as it will allow their patients to receive their interventional cardiac care at Greenwich Hospital. Letters of support from members of the Greenwich Hospital medical staff attest to physicians' endorsement of the proposed program and are included in Attachment V.

c. Explain why the proposal will not result in an unnecessary duplication of existing or approved health care services.

The proposal will not result in unnecessary duplication of existing or approved health care services. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital for the primary angioplasty service.

d. The record in this docket will include, in addition to other materials, the American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines. The Applicants may submit any comments in response to this evidence, which they deem appropriate.

Please see Attachment VI. Knowledge and processes related to elective angioplasty continue to evolve. As previously noted, increasing and significant evidence exists for elective angioplasty programs at facilities without on-site surgical backup. The November 7, 2011 updated ACC/AHA/SCAI angioplasty guidelines have upgraded the recommendation level for elective angioplasty programs without cardiac surgery back-up. Greenwich Hospital and Yale-New Haven Hospital adhere to these guidelines, which are incorporated into relevant policies and procedures.

e. If applicable to the proposal (e.g. establishment of cath lab without a cardiac surgical program), provide a copy of a signed agreement between the Applicant and a tertiary care facility. Identify patient selection guidelines, the process and protocols involved in the transfer of a patient requiring cardiac surgery, and joint quality assurance reviews and joint training.

A copy of the signed agreement between Greenwich Hospital and YNHH can be found in Attachment VII. The agreement addresses patient selection, emergency transfer, joint quality assurance and training.

f. Has the Applicant held any discussions with the local emergency medical service ("EMS") regarding the proposed service? Describe.

Greenwich Hospital had discussions with the Greenwich Emergency Services (GEMS) and the Emergency Medical Services companies servicing Port Chester, Rye and Harrison, New York about the proposed program, and received favorable responses from all parties.

3. Projected Volume

a. In table format, provide historical volumes (three full years and the current year-to-date) for each Applicant by service; by zip code; by inpatient/outpatient; and by unique physician identifier as applicable to the proposal.

<u>Volume by Service and Inpatient/Outpatient</u>
Historical volume for Greenwich Hospital primary angioplasties is shown in the table below.

Total Greenwich Hospital Primary Angioplasty Cases

	FY 2008	FY 2009	FY 2010	FY 2011	FY 2012*
Total Angioplasty	40	40	32	38	15
Note: All angioplasties are inpatient

b. If applicable, for the most recently completed fiscal year, identify the number of:

i. Patients with a diagnosis of ST-segment elevation acute myocardial infarction (AMI) that presented at the Hospital's emergency room

In FY 2011, there were 57 patients that presented to Greenwich Hospital's emergency department who triggered an MI Alert with a suspected diagnosis of ST-segment elevation acute myocardial infarction.

ii. Doses of thrombolytic medication, issued through its pharmacy, to patients with a diagnosis of AMI.

In FY 2011, there were zero doses of thrombolytic medication issued through the pharmacy to patients with diagnosis of AMI. In acute MI, thrombolytics are typically only used if emergency angioplasty cannot be done in a timely manner. Greenwich Hospital did not use thrombolytics for acute MI during the past year because the Hospital brought these patients to the cardiac catheterization lab in a timely fashion, which is the clinically preferred treatment for patients.

c. In table format, provide projected volumes (three full years) for each Applicant by service; by inpatient/outpatient; and by unique physician identifier as applicable to the proposal.

The tables below provides historical and three full years of projected volumes by inpatient/outpatient.

Due to the unscheduled nature of primary angioplasty cases and the scheduling rotation for the interventional cardiologists, it is difficult to project future volumes by unique physician identifier.

CON Elective Angioplasty Volume Projections

Angioplasty Volumes at Greenwich Hospital
Historical and Projected Volumes

d. Provide a detailed description of all assumptions used in the derivation/calculation of the projected volumes.

The angioplasty projections include primary angioplasty cases currently treated at the Hospital and elective angioplasty cases currently not treated at the Hospital.

Greenwich Hospital currently provides primary angioplasty to patients that meet the criteria for care. For the past several fiscal years, this volume has remained fairly stable. In FY11, the Hospital had 38 primary angioplasty cases. This is the same number as the four year average number of cases. This volume was projected to remain stable over the next several years. In the first quarter of FY12, the Hospital provided 15 primary angioplasties which would project to 60 annual primary angioplasties. To be conservative, projections were based on the last several fiscal years where 12 months of data was available for each year.

While the Hospital does not provide elective angioplasty at this time, there are patients who present to the Hospital each year that require elective angioplasty. These patients are either transferred or referred to another facility for care. The number of transfers or referrals for the past four fiscal years has been 54, 79, 64 and 59 respectively. Over the past four fiscal years, on average there had been 64 patients per year either transferred or referred to another facility for care. With the approval of this application, Greenwich Hospital would be able to provide elective angioplasty to the majority of these patients and thus save the patients an unnecessary transfer or referral to another facility. These patients are already part of the Greenwich Hospital physician referral patterns established at the Hospital that would continue when the Hospital is approved to provide elective angioplasty care. However, there is a small portion of patients that would need to be transferred or referred to another facility even if Greenwich Hospital was approved to provide elective angioplasty.

In the CPORT E trial, (discussed elsewhere in the CON) of patients who underwent primary angioplasty, 12% were excluded from randomization after consenting to the study, representing the subgroup who would be transferred to another facility. In reviewing the cases in FY09-11 that were either transferred or referred for care to another facility, it was felt that some of the cases would have been transferred or referred even if Greenwich Hospital was approved to provide elective angioplasty. These percentages for FY09-11 were respectively 12%, 16% and 22% for a three year average of 16.6%. For the projection of elective angioplasty at Greenwich Hospital, the conservative estimate of 16.6% was used, i.e. 83.4% of patients who had been transferred or referred to another facility in the past would be able to receive care at Greenwich Hospital. This percentage applied to the average of 64 patients per year transferred or referred to another facility yielded 53 patients in Year 1 who would be able to stay and receive their care at Greenwich Hospital. Again, to be conservative, this volume was projected to remain stable over the next several years.

Because Greenwich Hospital does not currently provide elective angioplasty services, physicians are reluctant to send their patients for cardiac catheterizations to the Hospital in case the patient will require an elective angioplasty and then have to be

transferred or referred to another facility. The Hospital conducted a telephone survey of cardiologists currently on the Hospital's medical staff. The cardiologists were asked to estimate the number of additional patients they might send to Greenwich Hospital for cardiac catheterizations if the Hospital received approval to offer elective angioplasty. In addition, some internal medicine physicians send patients directly for cardiac catheterizations to a hospital instead of to a cardiologist. The Hospital conducted a survey of the large internal medicine practices on the medical staff. These physicians were also asked to estimate the number of additional patients they might send to Greenwich Hospital.

Lastly, the cardiology practice that is part of the YNHHS cardiology program at Greenwich Hospital estimated the number of patients each year that they send directly to Yale-New Haven for cardiac catheterizations instead of to Greenwich Hospital. These patients numbered 25, 22, 21 and 25 in FY08-11 respectively for an average of 24 per year. These patients would use Greenwich Hospital if the Hospital provided elective angioplasty services. Based on the information above, 257 additional cardiac catheterizations were estimated to be sent to Greenwich Hospital for care if the Hospital provided elective angioplasty services. The surveyed physicians who indicated they would send additional cardiac catheterizations have practices located in Greenwich, Connecticut or in Westchester County, New York.

In order to estimate the number of angioplasties resulting from the additional cardiac catheterizations, the ratio of angioplasties to cardiac catheterizations was analyzed. Since primary angioplasties and elective angioplasties have the same codes, it was not possible to separate them into two categories so angioplasty volume includes both primary and elective angioplasty cases. Angioplasty volume and cardiac catheterization volume includes both inpatient and outpatient cases. New York angioplasty and cardiac catheterization outpatient historical volumes were not available from the state of New York for CY08 and for CY11 only the first five months of inpatient and outpatient data was available. Therefore, CY11 New York data was flat line projected to estimate the entire year.

The ratios of angioplasties to cardiac catheterizations were determined for Greenwich Hospital (35.4%), Yale-New Haven Hospital (45.3%), the state of Connecticut (36.3%) and the Greenwich Hospital service area (41.2%). The Greenwich Hospital average included patients transferred or referred to another facility. While the program at Greenwich Hospital will follow all of the policies, procedures and guidelines of the Yale-New Haven Heart and Vascular Center, the New Haven facility is a tertiary hospital and may see a higher rate of angioplasty/sicker patients. To be conservative, an average ratio (41.0%) of the Yale-New Haven Hospital ratio and state of Connecticut ratio was used to estimate the number of angioplasties resulting from the cardiac catheterizations. The 41.0% ratio was applied to the 256 potential angioplasties to yield an estimated 105 new referred angioplasty cases to Greenwich Hospital in Year 1 from cardiologists on the Hospital medical staff who would previously have sent the cases either to Yale-New Haven Hospital or a New York hospital. It is expected that this volume would increase 21 and 25 angioplasties respectively in Years 2 and 3 as the Greenwich Hospital program becomes established. The increases would represent less than 1 angioplasty per year from each of the

cardiologists on the medical staff of Greenwich Hospital. Since the patients will be referred by the cardiologists on the Greenwich Hospital medical staff, it is expected that the majority of patients will be from New York or Greenwich, Connecticut. The increase in volume results from several factors including the addition of New York interventional cardiologists who currently do not practice at Greenwich Hospital but have referral relationships with the cardiologists on the Hospital medical staff, increased physician comfort with elective angioplasty care at the Hospital and patient preference for the high quality care offered at Greenwich Hospital.

In FY11, inpatient angioplasties were 89.6% of total angioplasties according to the latest available data from the CHIME database. This percentage was used to estimate the distribution of angioplasties at Greenwich Hospital in Years 1, 2 and 3.

e. Provide a copy of any articles, studies, or reports that support the statements made in this application justifying need for the proposal, along with a brief explanation regarding the relevance of the selected articles.

In addition to previous studies and reports referenced, Attachment IX contains some additional supporting materials. Key points from each document are summarized below.

Document/Article	Key Points
Atlantic Cardiovascular Patient Outcomes Research Trial presentation	**"In hospitals without on-site cardiac surgery that complete a formal PCI development program, adhere to C-PORT participation requirements, and whose outcomes are monitored, non-primary PCI is safe and associated with similar rates of adverse events including mortality"**
American Heart Association /American Stroke Association CPORT-E Trial Summary	**Summarizes results of CPORT-E Trial: "Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without cardiac surgery capabilities fared as well as those in hospitals that did."**
2011 ACC/AHA/SCAI Guideline for Percutaneous Coronary Intervention	**Provides additional explanation and documentation of the 2011 guidelines and shows classification of recommendations and levels of evidence.**
The Advisory Board Daily Briefing On-site Surgery Not Necessary to Perform Elective PCI, November 18, 2010	**Summary of Atlantic CPORT-E Trial. Conclusion "The findings ultimately may prompt regulatory changes that could effectively decouple PCI and open heart surgery, allowing more flexibility for hospitals pursuing a regionalization strategy."**

f. Please identify the number of physicians that will be providing coverage for the proposed program. Explain whether the physicians will be full time with the proposed program or also providing coverage at other hospitals.

Physician coverage for the proposed elective angioplasty program will be similar to the existing 24/7 coverage for the primary angioplasty program. Coverage will be provided by privileged medical staff associated with either YSM Department of Cardiology, members of which currently practice at Greenwich Hospital as part of the existing primary angioplasty program, or members of the Greenwich Hospital medical staff with privileges in performing angioplasties. At this time, coverage will be provided by eleven interventional cardiologists from the Yale School of Medicine. At least one physician will be full time at Greenwich Hospital weekdays and on call nights and weekends. The on call physician will be in close proximity to Greenwich Hospital for immediate response to the Hospital during nights and weekends. When on call, the physician will only be covering Greenwich Hospital. The members of the YSM Section of Interventional Cardiology also provide coverage at Yale-New Haven Hospital, the West Haven VA and Lawrence & Memorial Hospital's primary angioplasty program.

4. Quality Measures

a. Submit a list of all key professional, administrative, clinical, and direct service personnel related to the proposal. Attach a copy of their Curriculum Vitae.

Please see Attachment X for copies of Curriculum Vitae.

<u>Greenwich Hospital</u>

- **Frank Corvino, President and CEO**
- **Eugene Colucci, CFO**
- **Quinton Friesen, Executive Vice President and COO**
- **Marc Kosak, Vice President, Administration**
- **Christopher Howes, M.D., Medical Director of PAMI Program and Interventional Cardiology at Greenwich Hospital, Assistant Professor of Medicine, Yale School of Medicine**

<u>Yale-New Haven Hospital</u>

- **Marna P. Borgstrom, Chief Executive Officer**
- **Richard D'Aquila, President and Chief Operating Officer**
- **James Staten, Senior Vice President, Finance and CFO**
- **Thomas Leary, Vice President, Physician Development**
- **Michael Simons, M.D., Chief, Section of Cardiovascular Medicine**
- **Henry Cabin, M.D., Associate Section Chief of Cardiology**
- **Francine LoRusso, RN, Director, Patient Services, Heart and Vascular Center**

b. Explain how the proposal contributes to the quality of health care delivery in the region.

The current population served through Greenwich Hospital's primary angioplasty program is limited to patients that present on an emergent basis with ST segment

elevation MI or new onset left bundle branch block. This proposal would provide local access to patients requiring interventional cardiology services on an elective and urgent basis as well as the emergent patients who currently have access to these services. Patients from the Greenwich Hospital service area that require elective angioplasty are currently required to go to another hospital to receive these services, which adds additional stress for patients and their families, particularly unnecessary due to the presence of highly qualified interventional cardiologists and staff available onsite. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital. As discussed in the public needs section, the current practice of transferring patients who require elective angioplasty has potential negative implications to patient care quality and safety. As well, the majority of these patients are transferred to Yale-New Haven Hospital, where they are treated by the same physicians from whom they would have received the same care at Greenwich Hospital if Greenwich Hospital was approved to provide elective angioplasty.

Greater System-wide clinical integration, through the proposed closer integration of Greenwich Hospital's cardiac services with the Yale-New Haven Heart & Vascular Center and partnership with the Yale School of Medicine will have a positive impact on the quality of health care delivery in the region. The Yale-New Haven Heart & Vascular Center will provide medical and clinical direction, education, training and management and oversight to ensure the delivery of the highest quality care. In addition, the use of the Epic common electronic medical record and combining best practices at both campuses to enhance clinical quality and patient safety through standardized procedures and practices.

<u>Greenwich Hospital's High Quality Cardiac Program</u>
The most recent ACC/AHA/SCAI guidelines have and will continue to guide Greenwich Hospital in the operation of its angioplasty program. A copy of the guidelines is attached (Attachment VI).

Greenwich Hospital participates in the National Cardiovascular Data Registry NCDR – CathPCI Registry®. Launched by the American College of Cardiology (ACC) in 1995, the "ACC National Cardiovascular Data Registry: (ACC-NCDR™) is a result of the ACC's exploration of various strategies for collecting and implementing clinical data in order to improve cardiovascular care. This database includes the implanted cardiac defibrillator registry as well as a heart catheterization registry (which further breaks down to both diagnostic and interventional procedures). The information gathered from this database allows the ACC to set benchmarks that enable facilities to see where they are deficient and therefore improve upon performance. There are currently 1,380 sites that participate in the catheterization registry.

In addition, both the primary angioplasty program, which has been in place at Greenwich Hospital since 2005, and the diagnostic cardiac catheterization laboratory, have achieved outcomes that are consistent with many larger tertiary facilities. For the four quarters ending mid-2011, 100% of STEMI patients received immediate angioplasty within 90 minutes, which meets/exceeds national standards for this measure. Other strong clinical outcomes of the Greenwich Hospital primary

angioplasty program, for the four quarters ending mid-2011, are shown in the following table.

National Cardiovascular Data Registry Institutional Outcomes
Executive Summary
Greenwich Hospital
Rolling Four Quarters Ending 2011 Q2

Section II: Quality Metrics			
Metric	Greenwich Hospital	All Hospitals 50th Percentile	All Hospitals 90th Percentile
PCI Process Metrics			
Median time to immediate PCI for STEMI patients (in minutes)	67.0	63.1	50.4
Proportion of STEMI patients receiving immediate PCI within 90"	100%	91.4%	100%
Proportion of patients with aspirin prescribed at discharge	100%	98.2%	99.9%
Proportion of patients with thienopyridine prescribed at discharge	100%	99.1%	100%
Statins prescribed at discharge	100%	91.5%	97.3%
Utilization Metrics			
Median post-procedure length of stay (in days) for PCI patients with STEMI	2.0	2.7	1.7

Source: National Cardiovascular Data Registry® – CathPCI Registry® - Executive Summary – Greenwich Hospital Compared to Rolling Four Quarters for All Hospitals Ending 2011Q2. Aggregation Date: September 30, 2011 Published Date: October 19, 2011

The ACC-NCDR database has limitations on the comparative use of its angioplasty data. However, at this time the ACC-NCDR data is the only benchmarking data set available to hospitals. The ACC-NCDR reports provide comparative benchmarking for all participating programs, and do not separately benchmark programs that provide only primary angioplasty such as Greenwich Hospital. As a result, the report shows an "apples to oranges" comparison of data. Greenwich Hospital's performance is benchmarked against programs that have significantly higher volumes that include elective angioplasty cases. As well, primary angioplasty cases tend to be more medically unstable in comparison to elective angioplasty cases. Greenwich Hospital contacted NCDR but the organization was not able to provide the Hospital with data listed separately for primary versus elective angioplasty. Greenwich Hospital's most recent complete ACC-NCDR report is included as Attachment XI. A letter from Greenwich Hospital to the Office of Health Care Access dated March 9, 2011 that discusses the limitations of comparing Greenwich Hospital's primary angioplasty outcomes with larger programs that offer elective angioplasty, is included as Attachment XII.

Even given the limitations of the angioplasty data, it is clear that Greenwich Hospital is providing essential cardiac care to patients with strong results. An elective angioplasty program is a logical and cost-efficient extension of the existing diagnostic cardiac catheterization and primary angioplasty program infrastructure, and would be

performed by many of the same expert physicians and staff, and in the same dedicated laboratories, as the existing programs.

c. Identify the Standard of Practice Guidelines that will be utilized in relation to the proposal. Attach copies of relevant sections and briefly describe how the Applicant proposes to meet each of the guidelines.

American College of Cardiology - Please see Attachment VI for the 2011 ACC/AHA/SCAI Guidelines and the 2007 SCAI Expert Consensus Document.

Quality and safety standards for the elective angioplasty program are paramount. As with the primary angioplasty program, the Hospital will continue to be part of the Yale-New Haven Heart and Vascular Center and will continue to draw on the collective clinical resources and experience of the Center and comply with all standards, protocols, policies, procedures and quality assessments. Yale-New Haven Heart and Vascular Center staff will continue to provide clinical oversight, educational training and quality review services to ensure high quality outcomes. The medical direction for the program will continue to be provided by the appointed YSM interventional cardiologist. All of this ensures one standard of care across the Yale New Haven Health System and the highest possible angioplasty care provided at Greenwich Hospital. The clinical experience gained from the additional volume of the elective angioplasty program will serve to further improve the clinical competency of the program staff.

Greenwich Hospital will meet the guidelines through clinical policies and procedures, medical staff credentialing and quality assurance processes. In addition, it is important to note that the interventional cardiology clinical faculty from the Yale School of Medicine, who will perform the majority of elective angioplasty procedures at Greenwich Hospital, are highly skilled with considerable experience in this procedure. At the various sites where these physicians practice (including Yale-New Haven Hospital, Greenwich Hospital, the West Haven VA and Lawrence & Memorial Hospital), they performed more than the guideline recommended procedures in Fiscal Year 2011.

5. Organizational and Financial Information

a. Identify the Applicant's ownership type(s) (e.g. Corporation, PC, LLC, etc.).

The ownership type is Corporation.

b. Does the Applicant have non-profit status?

☒ Yes (Provide documentation) ☐ No

Please see Attachment XIII for documentation of non-profit status.

c. Provide a copy of the State of Connecticut, Department of Public Health license(s) currently

held by the Applicant and indicate any additional licensure categories being sought in relation to the proposal.

Please see Attachment XIV for copies of licenses.

d. Financial Statements

i. If the Applicant is a Connecticut hospital: Pursuant to Section 19a-644, C.G.S., each hospital licensed by the Department of Public Health is required to file with OHCA copies of the hospital's audited financial statements. If the hospital has filed its most recently completed fiscal year audited financial statements, the hospital may reference that filing for this proposal.

Copies of both YNHH's and GH's audited financial statements for FY 2010 are currently on file with OHCA.

ii. If the Applicant is not a Connecticut hospital (other health care facilities): Audited financial statements for the most recently completed fiscal year. If audited financial statements do not exist, in lieu of audited financial statements, provide other financial documentation (e.g. unaudited balance sheet, statement of operations, tax return, or other set of books.)
Not applicable.

e. Submit a final version of all capital expenditures/costs as follows:

Table 2: Proposed Capital Expenditures/Costs

Medical Equipment Purchase	**$ 0**
Imaging Equipment Purchase	
Non-Medical Equipment Purchase	
Land/Building Purchase *	
Construction/Renovation **	
Other Non-Construction (Specify)	
Total Capital Expenditure (TCE)	**$ 0**
Medical Equipment Lease (Fair Market Value) ***	
Imaging Equipment Lease (Fair Market Value) ***	
Non-Medical Equipment Lease (Fair Market Value) ***	
Fair Market Value of Space ***	
Total Capital Cost (TCC)	**$ 0**
Total Project Cost (TCE + TCC)	**$ 0**
Capitalized Financing Costs (Informational Purpose Only)	
Total Capital Expenditure with Cap. Fin. Costs	**$ 0**

* If the proposal involves a land/building purchase, attach a real estate property appraisal including the amount; the useful life of the building; and a schedule of depreciation.
** If the proposal involves construction/renovations, attach a description of the proposed building work, including the gross square feet; existing and proposed floor plans; commencement date for the construction/
*** If the proposal involves a capital or operating equipment lease and/or purchase, attach a vendor quote or invoice; schedule of depreciation; useful life of the equipment; and anticipated residual value at the end of the lease or loan term.

Not applicable. There are no capital costs associated with the proposal.

f. List all funding or financing sources for the proposal and the dollar amount of each. Provide applicable details such as interest rate; term; monthly payment; pledges and funds received to date; letter of interest or approval from a lending institution.

Not applicable. The proposal does not include any incremental capital costs; therefore, no funding or financing is required.

g. Demonstrate how this proposal will affect the financial strength of the state's health care system.

This proposal will result in lower costs resulting from a decrease in patient transfers and a second procedure for some patients. Through the fuller use of its existing angioplasty infrastructure at Greenwich Hospital, including physicians and staff, more efficient care and enhanced patient quality and safety will result. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital.

6. Patient Population Mix: Current and Projected

a. Provide the current and projected patient population mix (based on the number of patients, not based on revenue) with the CON proposal for the proposed program.

Table 3: Patient Population Mix

	Current** FY ***	Year 1 FY ***	Year 2 FY ***	Year 3 FY ***
Medicare*	40.5%	40.5%	40.5%	40.5%
Medicaid*	5.4%	5.4%	5.4%	5.4%
CHAMPUS & TriCare				
Total Government	**45.9%**	**45.9%**	**45.9%**	**45.9%**
Commercial Insurers*	48.7%	48.7%	48.7%	48.7%
Uninsured	5.4%	5.4%	5.4%	5.4%
Workers Compensation				
Total Non-Government	**54.1%**	**54.1%**	**54.1%**	**54.1%**
Total Payer Mix	**100.0%**	**100.0%**	**100.0%**	**100.0%**

* Includes managed care activity.
** New programs may leave the "current" column blank.
*** Fill in years. Ensure the period covered by this table corresponds to the period covered in the projections provided.

b. Provide the basis for/assumptions used to project the patient population mix.

The current population mix for the current cases performed at the hospital was utilized in the projections.

7. Financial Attachments I & II

a. Provide a summary of revenue, expense, and volume statistics, without the CON project, incremental to the CON project, and with the CON project. **Complete Financial Attachment I.** (Note that the actual results for the fiscal year reported in the first column must agree with the Applicant's audited financial statements.) The projections must include the first three full fiscal years of the project.

Please see Attachment XV.

b. Provide a three year projection of incremental revenue, expense, and volume statistics attributable to the proposal by payer. **Complete Financial Attachment II.** The projections must include the first three full fiscal years of the project.

Please see Attachment XVI.

c. Provide the assumptions utilized in developing **both Financial Attachments I and II** (e.g., full-time equivalents, volume statistics, other expenses, revenue and expense % increases, project commencement of operation date, etc.).

Please see Attachment XVII.

d. Provide documentation or the basis to support the proposed rates for each of the FYs as reported in Financial Attachment II. Provide a copy of the rate schedule for the proposed service(s).

Rates for the proposed service will be approximately the same as the current service.

e. Provide the minimum number of units required to show an incremental gain from operations for each fiscal year.

Each additional incremental case produces an incremental gain.

f. Explain any projected incremental losses from operations contained in the financial projections that result from the implementation and operation of the CON proposal.

No incremental losses from operations are anticipated.

g. Describe how this proposal is cost effective.

The proposed elective angioplasty program maximizes use of the existing high-cost infrastructure of the primary angioplasty program and permits existing and available highly qualified expert physicians and staff to perform both primary and elective angioplasties for which they have been trained and are qualified to perform. In addition, as noted above, through System-wide integration, coordination of care practices and standardization, more cost effectiveness and evidence-based care will be provided.

Elective angioplasty patients can fare well in experienced hospitals with no heart surgery capabilities

American Heart Association Late-Breaking Clinical Trial Report - Abstract: 18558 - EMBARGOED UNTIL 8AM ET November 14, 2011

Study Highlights:

- Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without heart surgery capabilities fared as well as those in hospitals that did.
- Both groups of patients had less than a 1 percent death rate.

ORLANDO, FLA., Nov. 14, 2011 — Patients who had non-emergency artery-opening angioplasty or stent implantation at experienced hospitals without on-site heart surgery capabilities fared no worse than those in surgery-equipped hospitals, according to late-breaking research presented at the American Heart Association's Scientific Sessions 2011.

In a study from the Cardiovascular Patient Outcomes Research Team (CPORT), researchers randomly assigned 13,995 patients to have their procedure done at a hospital with cardiac surgery capabilities and 4,523 patients at hospitals without.

The death rate after six weeks was almost the same for each group — just under 1 percent, researchers said. Furthermore, neither group were more likely to need emergency heart bypass surgery.

If emergency surgery was required at a hospital without on-site surgery, the patient was transferred urgently.

The American College of Cardiology Foundation/American Heart Association guidelines have recommended that elective angioplasty and stent implantation be done at hospitals with cardiac surgery facilities in the same building in case emergency surgery is needed.

In this study, emergency surgery was needed for 20 of the 13,995 patients undergoing procedures at hospitals without on-site surgery and 10 of the 4,523 patients treated at hospitals with surgery available.

However, the need for emergency surgery during these procedures has plummeted over the last few decades, said Thomas Aversano, M.D., the study's lead researcher and associate professor of medicine at Johns Hopkins Medical Institutions in Baltimore, Md.

"In the 1980s, the need for cardiac surgery was high; 5 percent to 7 percent of these cases could require emergency open heart or bypass surgery," Aversano said. "The cardiac operating room was kept open in the event a complication requiring surgery occurred. Now it's one in 500 or one in 1,000. It's very uncommon."

In this carefully structured study, the 60 hospitals without cardiac surgery capabilities had to be able to annually perform at least 200 angioplasties or stent implantations, also called percutaneous coronary interventions or PCI. The physicians doing the procedures were required to be performing more than 75 PCI cases annually. All centers underwent a formally developed PCI program.

Some states restrict hospitals from performing these procedures without on-site surgery, except for an emergency, Aversano said.

"We do not support the spread of angioplasty to every hospital in the United States," he said. "However, it can be burdensome and costly for all medical centers to have cardiac surgery capabilities. And it doesn't make sense to create more surgical programs just to support the angioplasty programs."

He said regional healthcare planners can use the data from the study to make informed decisions about which hospitals should have PCI capability, with the aim of improving quality, improving access and lowering costs.

The study provides only short-term results, but early next year, researchers will have data revealing how patients fared nine months after the procedure. They said this will be important in assessing the overall effect of these two systems of care on ultimate patient outcomes.

Co-authors are the C-PORT investigators.

Outcomes of Nonemergent Percutaneous Coronary Intervention With and Without On-site Surgical Backup: A Meta-Analysis

Param Puneet Singh, MD,* Mukesh Singh, MD, Updesh Singh Bedi, MD, Sasikanth Adigopula, MD, Sarabjeet Singh, MD, Vamsi Kodumuri, MD, Janos Molnar, MD, Aziz Ahmed, MD, Rohit Arora, MD, and Sandeep Khosla, MD

Despite major advances in percutaneous coronary intervention (PCI) techniques, the current guidelines recommend against elective PCI at hospitals without on-site cardiac surgery backup. Nonetheless, an increasing number of hospitals without on-site cardiac surgery in the United States have developed programs for elective PCI. Studies evaluating outcome in this setting have yielded mixed results, leaving the question unanswered. Hence, a meta-analysis comparing outcomes of nonemergent PCI in hospitals with and without on-site surgical backup was performed. A systematic review of literature identified four studies involving 6817 patients. Three clinical end points were extracted from each study and included in-hospital death, myocardial infarction, and the need for emergency coronary artery bypass grafting. The studies were homogenous for each outcome studied. Therefore, the combined relative risks (RRs) across all the studies and the 95% confidence intervals (CIs) were computed using the Mantel-Haenszel fixed-effect model. A two-sided alpha error less than 0.05 was considered to be statistically significant. Compared with facilities with on-site surgical backup, the risk of in-hospital death (RR, 2.7; CI, 0.6–12.9; $P = 0.18$), nonfatal myocardial infarction (RR, 1.3; CI, 0.7– 2.2; $P = 0.29$), and need of emergent coronary artery bypass grafting (RR, 0.46; CI, 0.06– 3.1; $P = 0.43$) was similar in those lacking on-site surgical backup. The present meta-analysis suggests that there is no difference in the outcome with regard to risk of nonfatal myocardial infarction, need for emergency coronary artery bypass grafting, and the risk of death in patients undergoing elective PCI in hospitals with and without on-site cardiac surgery backup.

Keywords: onsite backup surgery, percutaneous coronary intervention

INTRODUCTION

Percutaneous coronary interventions (PCI) were introduced for the first time in 1977 by Andreas Gruntzig.[1] Since then, many technologic and pharmacologic advances in PCI have been made. Steerable guidewires, coronary artery stents,[2] and new antiplatelet therapies have improved the success rate of PCI procedures and significantly reduced the risk of per-procedural complications needing urgent cardiac surgery. Recent studies have shown that the need for emergency cardiac surgery is now as low as 0.3% to 0.6%.[2,3] As a result, the number of procedures has increased worldwide,[4] and an increasing proportion of procedures are performed at centers without surgical backup.[5,6] Despite major advances in PCI technique, the current American College of Cardiology/American Heart Association/-Society of Cardiovascular Angiography and Intervention 2005 guidelines[7] for PCI recommend against elective PCI at hospitals without on-site cardiac surgery (Class III indication). Acknowledging this trend, the Society for Cardiovascular Angiography and Interventions recently issued an expert consensus statement that provides practice standards for elective PCI at hospitals

without on-site cardiac surgery.[8] Because of the conflicting literature on this subject, the question about safety of elective PCI at centers without surgical backup remains unanswered. Hence, a meta-analysis comparing outcomes of nonemergent or elective PCI in hospitals with and without on-site surgical backup was performed.

METHODS

We performed this review in accordance with the Quality of Reporting of Meta-analysis statement and the Consolidated Standards of Reporting Trials Group recommendations.[9]

Literature search

A systematic review of the medical literature was performed to identify studies evaluating the efficacy or adverse outcomes of combination therapy in patients with congestive heart failure, acute myocardial infarction, or high-risk diabetes mellitus. Eligible studies were identified by searching MEDLINE (January 1966–December 2008), EMBASE (January 1980–December 2006), the Cochrane Library (Controlled Trials Register and Database of Systematic Reviews, all years), the National Institute of Health Clinical Trials (http://www.clinicaltrials.gov), and the U.S. Food and Drug Administration web sites (http://www.FDA.gov) and relevant bibliographies.

Study selection

There was a written protocol with explicit inclusion and exclusion criteria, which was followed for all articles that were screened. All titles and abstracts from the results of our computerized search were reviewed by the authors for potential inclusion in our study. We also searched for relevant review articles and their bibliographies for articles. In addition to our computerized search, we manually reviewed the reference list of all retrieved articles to complete our search for randomized, controlled trials comparing outcome of PCI with and without surgical backup. Study selection process is outlined in Figure 1.

Studies were excluded if they did not meet the inclusion criteria. Those studies that were not done in human subjects, not randomized, published in nonpeer-reviewed journals, or with inadequate follow up were excluded from our analysis.

End points and definitions

Three clinical end points were extracted from each study and included: in-hospital death, nonfatal myocardial infarction (MI), and need for emergency coronary artery bypass surgery (CABG). End point definitions were those used in the individual trials. Death was defined as in-hospital mortality from any cause. MI was defined as enzymatic and electrocardiographic changes consistent with MI. Emergency CABG surgery was defined as unplanned surgical revascularization within 48 hours of PCI. All end points were assessed at the end of follow up of the trial.

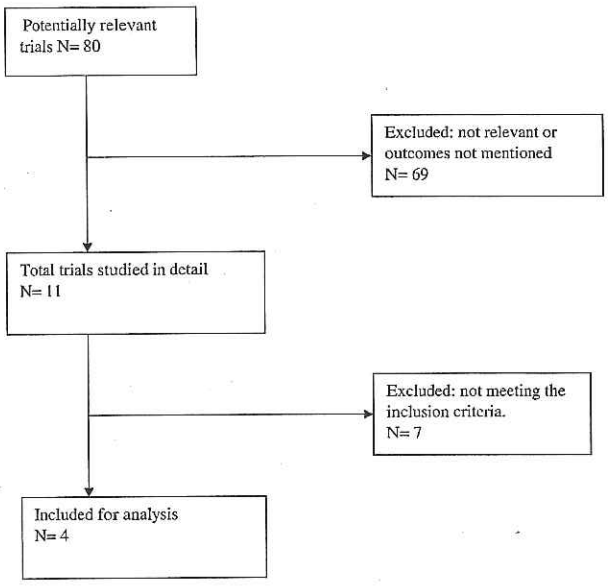

FIGURE 1. Trial selection and inclusion flow diagram.

Data extraction

The two authors (PS, MS) independently screened the titles and abstracts for eligibility. Full articles were retrieved for all titles for which abstracts were not available and for all abstracts that appeared to potentially fulfill the inclusion and exclusion criteria. It was decided that if there was a conflict between the two authors, then the study in question would be brought to the panel of all authors where the decision would be made for its inclusion. Data extraction was done independently by two authors. Each author tabulated important trial characteristics and assessed methodological quality (jaded score), including patient demographics such as age, study population, sample size diabetes, hypertension, and angiographic characteristics.

Statistical analysis

The statistical analysis was performed with the Comprehensive Meta-Analysis software package (Version CM 2.2; Biostat, Englewood, NJ). We calculated odds ratio for each study outcome to allow for pooling of similar outcomes. All the results are reported as the pooled odds ratio with 95% confidence interval (CI). Chi square test

Table 1. Results of heterogeneity analysis.

End Point	Q-value	df (Q)	*P* Value	I-squared	Result
In-hospital death	3.4	1	0.067	70.2	Homogenous
Nonfatal myocardial infarction	1.4	3	0.707	0.0	Homogenous
Emergency coronary artery bypass graft	2.0	1	0.155	50.7	Homogenous

was used to assess heterogeneity. The studies were homogenous for each outcome studied (Table 1). Therefore, the combined relative risks (RRs) across all the studies and the 95% CIs were computed using the Mantel-Haenszel fixed-effect model. A two-sided alpha error less than 0.05 was considered to be statistically significant.

Role of funding source

The funding source had no role in the design, conduct, or reporting of the study or in the decision to submit the manuscript for publication.

RESULTS

Data synthesis and study characteristics

Figure 1 represents the trial selection and inclusion flow diagram. After the initial search based as described previously, a total of 80 articles was considered as potentially relevant. After the title and abstract review, 69 of the 80 were excluded because they were not randomized, non-English trials, or did not meet our inclusion criteria. From the remaining 11, seven were excluded after full text review because there was inadequate follow up, the outcomes measured were different, or the study characteristics did not meet our inclusion criteria. Our search of abstracts from conference proceedings of the American College of Cardiology, American Heart Association, European Society of Cardiology, and Heart Failure Society of America did not reveal any additional studies that satisfied our inclusion and exclusion criteria. Our meta-analysis included the remaining four randomized, controlled trials involving 6817 patients.[10–13]

Baseline characteristics

Table 2 summarizes the study population characteristics of all the studies included for the analysis. All four studies were large randomized, controlled trials with adequate follow up. Mean duration of follow up was 31 months. Mean age of patients enrolled was 64 years. Allocation sequence generation and concealment were adequately described in all four studies. All the studies had two arms comparing the outcome of patients undergoing elective PCI at two centers with and without on-site cardiac surgery backup. In-hospital death and need for emergency surgery as outcomes were reported in two studies,[12,13] whereas non-fatal MI was reported in all four studies included in this meta-analysis.[10–13]

Clinical outcomes

Angiographic characteristics of patients in the included studies are given in Table 3. The outcomes measured in our analysis were in-hospital death, nonfatal MI, and need for emergent CABG.

In-Hospital Death

Compared with hospitals with surgical capability, there was no difference in the risk of in-hospital death in patients undergoing elective PCI at centers without surgical back up (RR, 2.7; CI, 0.6–12.9; $P = 0.18$) (Fig. 2).

LVEF less than 40%	SB	—	—	374 (19%)	92 (13%)
	NSB	—	—	59 (9%)	74 (10%)

MI, myocardial infarction; PCI, percutaneous coronary intervention; TIA, transient ischemic attack; CABG, coronary artery bypass grafting; PVD, peripheral vascular disease; DM, diabetes mellitus; HTN, hypertension; CKD, chronic kidney disease; CHF, congestive heart failure; LVEF, left ventricular ejection fraction; SB, on-site surgical backup group; NSB, no on-site surgical backup group.

Nonfatal Myocardial Infarction

The risk of nonfatal MI was similar in both groups of patients without any significant difference (RR, 1.3; CI, 0.7–2.2; $P = 0.29$) (Fig. 3).

Need for Emergent Coronary Artery Bypass Grafting

The risk for need for emergent CABG did not differ between the patients undergoing PCI at centers with and without surgical backup (RR, 0.46; CI, 0.06–3.1; $P = 0.43$) (Fig. 4).

DISCUSSION

Our meta-analysis shows that there is no difference in the incidence of in-hospital mortality, nonfatal MI, and

the need for emergency CABG in patients undergoing PCI at centers with and without surgical backup (Fig. 5). Overall, of 6817 patients in all four studies, total in-hospital deaths were 32 (0.47%). In the group with no surgical backup, in-hospital mortality was 0.13% (three of 2315 patients died), whereas in the group with on-site surgical backup, the in-hospital mortality rate was 0.6% (29 of 4502 patients died).

The purpose of cardiac surgical backup for PCI is to provide emergent hemodynamic support and revascularization to salvage complications that cannot be addressed by catheter-based techniques. PCI can be complicated by life-threatening hemodynamic and ischemic emergencies that can be addressed only by the availability of emergency cardiac surgery. The role of on-site cardiac surgical backup is twofold: on-site cardiac surgical backup provides prompt availability of cardiac surgical support in the event of a hemodynamic or ischemic emergency and on-site cardiac surgical backup is a surrogate for an institution's overall capability to provide a highly experienced and promptly available team to respond to a catheterization laboratory emergency.[14] Technical improvements in PCI instruments and techniques have led to the concept that the requirement for emergency cardiac surgery is sufficiently rare that PCI can be performed safely without on-site surgery. This has led to the development of elective angioplasty programs without on-site surgical coverage.

Cardiac surgical backup for PCI has evolved from a formal surgical standby in the 1980s to an informal arrangement of first-available operating room and, in some cases, off-site surgical backup.[15–21] With the advent of intracoronary stenting, there has been a decrease in the need for emergency CABG ranging between 0.4% and 2%.[2,3,21–28] Not surprisingly, emergency CABG surgery for a patient with an occluded or dissected coronary artery is associated with a higher mortality than elective surgery.[21,29–34] Emergency procedures are also associated with high rates of perioperative infarction and less frequent use of

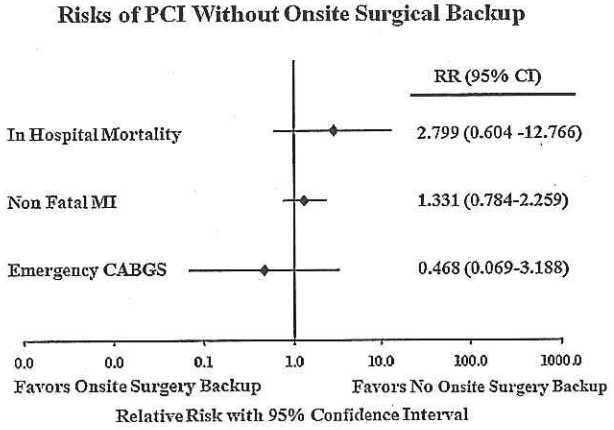

FIGURE 5. Summary figure.

arterial conduits. Complex coronary artery disease intervention, hemodynamic instability, and prolonged time to reperfusion are contributing factors to the increased risk of emergency bypass surgery.

A recently published report from analysis of National Cardiovascular Data Registry showed findings similar to our meta-analysis. This National Cardiovascular Data Registry data analysis showed that off-site PCI centers had similar observed procedure success, morbidity, emergency cardiac surgery rates, and mortality in cases that required emergency surgery. The risk-adjusted mortality rates in off-site PCI facilities were comparable to those of PCI centers that had cardiac surgery on-site regardless of whether PCI was performed as primary therapy for ST-elevation MI or in a nonprimary setting.[35]

Like with any meta-analysis, our analysis has limitations inherent to such analysis. Meta-analyses have inherent methodological limitations in that summary data are pooled from studies of different designs. The study population used in all the trials, although being somewhat similar, is not exactly the same. Although we detected no significant heterogeneity, a meta-analysis cannot replace large, well-conducted randomized trials as evidence for and against an intervention.

Our meta-analysis adds to the current body of literature on PCI by considering between study heterogeneity, bias, consistency of outcomes among studies and inclusion of large recent studies. This meta-analysis shows that there is no difference in the outcome with regard to risk of nonfatal MI, need for emergency CABG, and the risk of death in patients undergoing elective PCI in hospitals with and without on-site cardiac surgery backup.

Percutaneous Coronary Interventions in Facilities Without Cardiac Surgery On Site: A Report From the National Cardiovascular Data Registry (NCDR)

Michael A. Kutcher, MD,* Lloyd W. Klein, MD,† Fang-Shu Ou, MS,‡ Thomas P. Wharton, JR, MD,§ Gregory J. Dehmer, MD,‖ Mandeep Singh, MD, MPH,¶ H. Vernon Anderson, MD,# John S. Rumsfeld, MD, PHD,** William S. Weintraub, MD,†† Richard E. Shaw, PHD,‡‡ Matthew T. Sacrinty, MPH,* Albert Woodward, PHD, MBA,§§ Eric D. Peterson, MD, MPH,‡ Ralph G. Brindis, MD, MPH,‖‖ on behalf of the National Cardiovascular Data Registry (NCDR)

Since the introduction of percutaneous coronary intervention (PCI) in 1977 by Andreas Gruntzig (1), the presence of cardiac surgery backup on site has been a recommended practice to treat the potential of life-threatening complications. As a result of major improvements in technology and pharmacology, the need for emergency cardiac surgery is now infrequent (0.3% to 0.6%) (2,3). Moreover, primary PCI has been accepted as superior to fibrinolytic therapy for ST-segment elevation myocardial infarction (STEMI) (4). These developments have provided the justification for some hospitals without cardiac surgery to develop PCI programs based on a strategy to provide more rapid care for STEMI (5,6) and to increase the availability of PCI to patients in geographically underserved areas.

Favorable outcomes for primary PCI performed in facilities without cardiac surgery backup on site have been reported (7–9). In addition, smaller observational studies have extended this concept to both primary and elective PCI (10–14), and even PCI limited to elective cases (15). However, there are few large studies that have directly compared the procedural outcomes of both primary and elective PCI at facilities without cardiac surgery on site with those that have traditional surgery on site (16–18). Because of the conflicting literature on this subject, the American College of Cardiology (ACC), American Heart Association (AHA), and Society for Cardiovascular Angiography and Interventions (SCAI) 2005 PCI guidelines continue to designate primary PCI a Class IIb indication (may be considered), and elective PCI a Class III indication (not recommended) when performed at facilities without surgical backup on site (19). The 2007 PCI guideline focused update did not address or change these designations (20). Despite

Data analysis was performed by the Duke Clinical Research Institute with funding from the National Cardiovascular Data Registry. Drs. Kutcher and Klein perform percutaneous coronary intervention (PCI) at facilities that have on-site cardiac surgery. Dr. Wharton is a consultant to Corazon, The Heart and Vascular Experts, and performs PCI at a facility that does not have on-site cardiac surgery. Dr. Dehmer is Chief, Division of Cardiology, Texas A&M College of Medicine, Scott & White HealthCare, which includes facilities that have on-site cardiac surgery and facilities that do not. Dr. Singh performs PCI at Mayo Clinic facilities that have on-site cardiac surgery and facilities that do not. Dr. Anderson performs PCI at a facility that has on-site cardiac surgery.

these classifications, the number of PCI programs in the U.S. without surgery on site has increased significantly over the past several years (21). Recently, a SCAI expert panel outlined practical consensus principles for PCI performed at facilities without surgery on site, while not specifically encouraging or endorsing this practice (22).

The National Cardiovascular Data Registry (NCDR) was established by the ACC to proactively monitor and assess the clinical practice of cardiology in the U.S. (23). The NCDR CathPCI Registry, cosponsored by the ACC and SCAI, offers its participant institutions data field definitions, uniform data entry, secure transmission requirements, a data quality program, and risk-adjustment algorithms (24–26). Therefore, this registry provides an excellent resource of comparative data, in a relative contemporary clinical setting, to address the controversy over PCI at facilities without surgical backup on site.

Abbreviations and Acronyms

ACC = American College of Cardiology
AHA = American Heart Association
CABG = coronary artery bypass graft surgery
IABP = intra-aortic balloon pump
MI = myocardial infarction
NSTEMI = non–ST-segment myocardial infarction
PCI = percutaneous coronary intervention
SCAI = Society for Cardiovascular Angiography and Interventions
STEMI = ST-segment elevation myocardial infarction

Methods

Study population. Clinical characteristics and in-hospital outcomes were assessed in consecutive PCI cases reported to the NCDR CathPCI Registry from January 1, 2004, to March 30, 2006. Standardized NCDR version 3.04 definitions and data fields were used by all participating sites (27). The analysis cohort consisted of 308,161 patients from 465 PCI-capable facilities. Of these, 8,736 patients had PCI performed at 60 institutions in which it was verified there was no surgical backup on site within the buildings or campus that constituted the facility (off-site facility). The remaining 299,425 patients underwent PCI at 405 facilities that had cardiac surgery on site (on-site facility). Off-site PCI facilities comprised 13% of sites and 3% of patients in the NCDR CathPCI Registry during the study period.

Definitions. The primary outcomes for analysis were the incidence of emergency surgery and in-hospital death from all causes after PCI. Emergency surgery was defined as coronary artery bypass graft (CABG) surgery performed after PCI in which there was evidence of active ischemia or mechanical dysfunction (emergency), or if the patient required cardiopulmonary resuscitation en route to the operating room or before anesthesia (emergent/salvage). Secondary outcomes included procedure success, total complications (any general, bleeding, or vascular complications), and reperfusion time in cases of primary PCI for STEMI.

Off-site data clarification. During initial analysis, variations in 2 data fields unique to off-site PCI programs were noted. The field "CABG during this admission" permitted entry of only 1 category. In off-site centers, there was a disproportionately low incidence of "emergency" surgery, but a proportionately large number of patients "transferred for CABG" entered in this field. In addition, "transfer" patients could be counted as "alive" in the data field "discharge status" from an off-site center, but this opened the potential that a subsequent death after emergency surgery at the outside surgical center may not have been captured.

To resolve these issues, we conducted a data clarification project. Off-site centers with specific data points in question were queried to clarify whether a "transfer for CABG" data point was for elective or emergency surgery, and to verify the eventual survival at the off-site surgical center. This effort also provided an opportunity to gather additional information by a Capabilities Survey to reaffirm a true off-site status and to assess organization, staffing, and logistics. All of the off-site programs were invited to fill out the survey form, even those sites in which data clarification was not necessary.

Of the 8,736 patients undergoing PCI in off-site centers, 172 (2%) patients from 43 sites required data clarification regarding transfer surgery or mortality status. Of these 43 sites, 38 (88%) sites were able to clarify CABG status and/or mortality information for 154 of the 172 (90%) patients. For the 18 patients (0.2% of 8,736) whose transfer or mortality data were not clarified, if CABG status was uncertain, the original record entry was used for the CABG status-related analysis. If the subsequent mortality at the receiving surgery center could not be clarified, these patients were not included in the analysis of observed or risk-adjusted mortality.

Statistical analysis. Data analysis was performed by the Duke Clinical Research Institute. For descriptive analyses, institutional comparisons between off- and on-site PCI centers were made based on hospital characteristics. Comparisons between patients were made based on clinical characteristics, treatment profiles, procedural details, and clinical outcomes. These aggregates were further divided and analysis performed in patients who underwent primary PCI as first-line therapy for reperfusion in the presence of STEMI, and to the remainder of patients who underwent PCI in a nonprimary setting. Continuous variables are presented as mean with SD or as frequencies with percentages in each pre-specified category. Categorical variables are expressed as frequencies with percentages. To test for independence of patients' baseline characteristics, in-hospital care patterns and outcomes with respect to off-site versus on-site centers, the Wilcoxon rank-sum test was used for continuous variables, and the Pearson chi-square test was used for categorical variables.

A multivariable logistic regression model was then used to estimate the risk-adjusted association between on-site versus off-site PCI center surgical status and primary outcomes. Variables adjusted to mortality in-

cluded age, sex, insulin-treated diabetes mellitus, hypercholesterolemia, hypertension, dialysis, cerebrovascular disease, chronic lung disease, peripheral vascular disease, congestive heart failure, prior CABG, prior PCI, prior myocardial infarction (MI), cardiogenic shock at presentation, MI status (STEMI, non–ST-segment myocardial infarction [NSTEMI], and no MI), pre-operative intra-aortic balloon pump (IABP), PCI status (rescue, emergent, urgent, and elective), subacute thrombosis in a major artery, any treated lesion in left main artery, any treated lesion with pre-procedure stenosis 100%, any treated lesion with pre-procedure Thrombolysis In Myocardial Infarction (TIMI) flow grade 0, any treated lesion with high/C risk characteristics (see definition, bottom legend, Table 1), and total number of lesions treated. Variables adjusted to emergency CABG included cardiogenic shock, MI status (STEMI, NSTEMI, and no MI), pre-operative IABP, PCI status (rescue, emergent, urgent, and elective), and any treated left main artery lesion.

The Generalized Estimate Equation method (28) was applied to account for within-hospital clustering, considering patients at the same hospital are more likely to have similar responses relative to patients in other hospitals (i.e., within-center correlation for response). This method produces estimates comparable to those from ordinary logistic regression, but estimated variances are adjusted for the correlation of outcomes within each hospital.

Because not all off-site PCI center patient mortality data could be clarified, a sensitivity analysis was performed. This analysis utilized the same multivariable logistic regression model but imputed data to either of the following: patients with missing mortality data were considered either as all had died (worst scenario) or as all were alive (best scenario) on discharge.

Results

Institutional characteristics. Institutional characteristics are shown in Table 2. Compared with on-site centers, off-site PCI facilities had smaller bed capacity, were more likely to be located in nonurban areas, and had lower annual total PCI and primary PCI volume ($p < 0.001$). Overall, 43 (72%) of the off-site programs performed <200 total PCIs per year, and only 3 sites (5%) had >400 cases, suggesting that it was unlikely the outcomes were preferentially influenced by a few large-volume centers. The recommended volume standard of 36 or more primary PCIs per year (19) was achieved by 42% of the off-site programs compared with 80% of the on-site centers ($p < 0.001$).

Off-site capabilities survey. The survey (Table 3) was completed by 53 of the 60 off-site PCI facilities (88%). Approximately one-quarter of the centers had travel distances >40 miles and transit times (estimated driving or flight) >30 min. This information also reaffirmed that these were true off-site programs and did not have surgery back-up nearby in the next building. Full 24-h, 7-day coverage for PCI was provided by 92% of the sites. Both primary and elective PCI were performed in 79% of the centers, and none of the programs performed only elective PCI. Descriptive demographics regarding the organization of technical staff, interventional cardiologists, and transpor-

Data are n (%) unless otherwise indicated. *14 patients not included due to missing value for variable "Acute PCI." †High risk C lesion includes any of the following: diffuse (length >20 mm), excessive tortuosity of proximal segment, extremely angulated segments >90 degrees, total occlusions >3 months old and/or bridging collaterals, inability to protect major side branches, and degenerated vein grafts with friable lesions.

CABG = coronary artery bypass grafting; CHF = congestive heart failure; MI = myocardial infarction; PCI = percutaneous coronary intervention; SVG = saphenous vein graft.

tation modalities are further outlined in Table 3. Of note, 81% of the off-site programs reported that their interventional operators also rotated and performed PCI at on-site facilities.

Clinical characteristics. Clinical characteristics are shown in Table 1. In aggregate, on-site PCI centers generally treated patients with more risk factors and performed a greater percentage of PCI in multiple-lesion (33% vs. 29%, $p < 0.001$), saphenous vein graft (7% vs. 5%, $p < 0.001$), and higher lesion-risk cases (41% vs. 39%, $p = 0.001$). This difference was more pronounced in patients who underwent nonprimary PCI. In contrast, off-site facilities had a greater incidence of patients who had a clinical presentation of STEMI or NSTEMI (41% vs. 29%, $p < 0.001$) (Fig. 1).

Observed unadjusted procedural outcomes. Observed unadjusted procedural outcomes are shown in Table 4. Off-site facilities had slightly higher aggregate procedural success (94% vs. 93%, $p = 0.010$), predominantly due to higher success rates in nonprimary PCI cases. Aggregate total complications were similar in both off- and on-site facilities (6.5% vs. 6.3%), but off-site programs tended to have more bleeding events, and on-site more vascular complications. Off-site programs had fewer total complications in primary PCI (11.6% vs. 13.4%, $p = 0.029$) and had lower general (2.6% vs. 3.3%, $p = 0.001$) and vascular (0.8% vs. 1.1%, $p = 0.017$) complication rates in nonprimary PCI patients compared with on-site facilities.

In the overall PCI cohort, there was no significant difference in the incidence of emergency CABG surgery (0.3% vs. 0.4%, $p = 0.271$) or mortality with emergency CABG (13.6% vs. 12.8%, $p = 0.907$) between off- and on-site facilities, respectively. There was no difference in either of these variables when the analysis was stratified into primary PCI and nonprimary PCI patients. Although the unadjusted aggregate mortality rate was higher in off-site facilities (1.7% vs. 1.2%, $p < 0.001$) and appeared to be confined to patients who did not require emergency surgery, this difference did not persist when stratified by primary or nonprimary PCI. This increased unadjusted aggregate mortality was most likely due to a higher proportion of primary PCI patients (22% vs. 10%, $p < 0.001$) and STEMI and NSTEMI presentations (41% vs. 29%, $p < 0.001$) in off-site compared with on-site programs, respectively.

Primary PCI reperfusion times in nontransferred patients were significantly shorter in off-site PCI centers (mean 2.1 ± 5.1 h, median 1.4 h) compared with on-site (mean 2.6 ± 8.4 h, median 1.5 h, $p < 0.001$). These "reperfusion times" were defined as the time of arrival at the facility to the time of first treatment device deployment (27). Although both groups followed the same definition, these data were collected before there were major national quality

improvement initiatives and attention to the detailed measurements of true "door-to-balloon" times. Therefore, these times do not reflect the current door-to-balloon standards.

Risk-adjusted outcomes. After risk adjustment, there were no mortality differences between off- and on-site facilities among total PCI patients, primary PCI patients, nonprimary PCI patients, or patients who did not require emergency surgery (Fig. 2). There was a higher risk-adjusted odds of emergency surgery in on-site PCI centers (odds ratio: 0.60 [95% confidence interval: 0.37 to 0.98], $p = 0.042$).

A sensitivity analysis was performed comprising models that imputed missing mortality from off-site centers to 2 potential scenarios. Although the point estimate changed from 0.88 to 1.21, the confidence intervals surrounding these estimates were not statistically significant between off- and on-site facilities under either of these extreme assumptions.

Discussion

This study represents the largest and most comprehensive clinical comparison of PCI centers in the U.S. with and without cardiac surgery support on site. Despite lower annual PCI procedural volumes and more patients presenting with MI subsets, off-site PCI facilities reporting to the NCDR CathPCI Registry had similar rates of procedural success, morbidity, emergency surgery, and risk-adjusted mortality when compared with on-site PCI centers. These results persisted whether PCI was performed as primary therapy for STEMI or in a less urgent nonprimary PCI setting. In addition, the off-site Capabilities Survey in this study provided more descriptive information than has been previously reported in the literature regarding the organization and logistics of established off-site PCI programs.

It is important to contrast this study with the few large comparative reports in the literature. Wennberg et al. (16) found no difference in risk-adjusted mortality for primary PCI at facilities without surgery backup on site, but an increase in mortality for nonprimary/rescue PCI, particularly at very low-volume programs (<50 Medicare PCIs per year). Although their study had more hospitals without surgery on site (n = 178) and similar patient volumes (n = 8,168), the time period was from 1999 to 2001, and the data were derived from coded admission/discharge billing diagnoses confined to the Medicare population. In contrast, our study was based on well-defined contemporary clinical parameters and included clarification of ambiguous transfer data from the off-site PCI programs. We found no significant difference for risk-adjusted mortality between centers with and without surgery on site, in either primary or nonprimary PCI patients.

Ting et al. (17) previously reported comparable acute and long-term outcomes for both primary and elective PCI in a propensity score analysis of 1,007 cases from a PCI center without surgery on site matched to the same number of patients from a center with surgery on site. Of note, these Mayo Clinic facilities did not participate in the NCDR, and thus their patients were not included in our analysis.

Finally, in a recent report based on SCAAR (Swedish Coronary Angiography and Angioplasty Registry), Carlsson et al. (18) compared 8,838 PCI procedures from 14 PCI facilities that did not have cardiac surgery on site to 25,525 procedures from 10 PCI centers that did have surgery on site. Their analysis was adjusted for baseline variables, and demonstrated comparable 30-day and 1-year mortality and morbidity outcomes for both primary PCI and nonacute PCI. Although different variables were used in our risk-

Procedure success was defined as residual stenosis <50% with Thrombolysis In Myocardial Infarction flow grade 3 and minimal decrease in stenosis ≤20% in all lesions attempted. Total complications was defined as any of the following complications: general complications: periprocedural MI, cardiogenic shock, congestive heart failure, cerebrovascular accident, tamponade, thrombocytopenia, contrast reaction, renal failure; bleeding complications: bleeding at the access site, retroperitoneal, gastrointestinal, genitourinary, or other; vascular complications: access site occlusion, peripheral embolization, arterial dissection, arterial pseudoaneurysm, or arterio-venous fistula. Primary PCI was defined as PCI performed as first-line therapy for reperfusion in the presence of STEMI; does not include rescue or facilitated PCI or PCI for non-STEMI. Reperfusion time indicates time of arrival to facility to time of first intracoronary treatment device deployment. *14 patients not included due to missing value for variable "Acute PCI." †Clarified data.

Abbreviations as in Tables 1 and 2.

adjusted model, the in-hospital mortality/morbidity results are similar to these 2 studies.

The nonprimary PCI patient cohort in our study is not a reflection of purely elective PCI, as this group includes some patients who presented with acute coronary syndromes, NSTEMI, or after STEMI. However, the consideration of this group as "nonurgent" and a reasonable surrogate for elective PCI is consistent with the analyses done in the literature cited in the preceding text. In our study, the differentiation of patients in off-site versus on-site PCI centers into primary PCI and nonprimary PCI permitted a more comprehensive assessment and risk-adjustment analysis of the major clinical end points.

Within our study cohort, the aggregate incidence of emergency surgery was comparably low at off- and on-site PCI facilities (0.3% to 0.4%, respectively) and consistent with contemporary studies (2,3). When emergency surgery was necessary, the mortality rate was similarly high between off- (13.6%) and on-site (12.8%) facilities, and comparable to that reported in prior literature (2,3).

There have been concerns that off-site PCI facilities may tend to keep some borderline stable patients with suboptimal procedural results rather than initiate the logistics of emergency transfer to an outside surgical center. These patients may have adverse outcomes, as seems to be suggested by the aggregate unadjusted mortality rate in our study. However, in the risk-adjusted analyses, there was comparable in-hospital mortality for those off-site patients who were not transferred for emergency surgery.

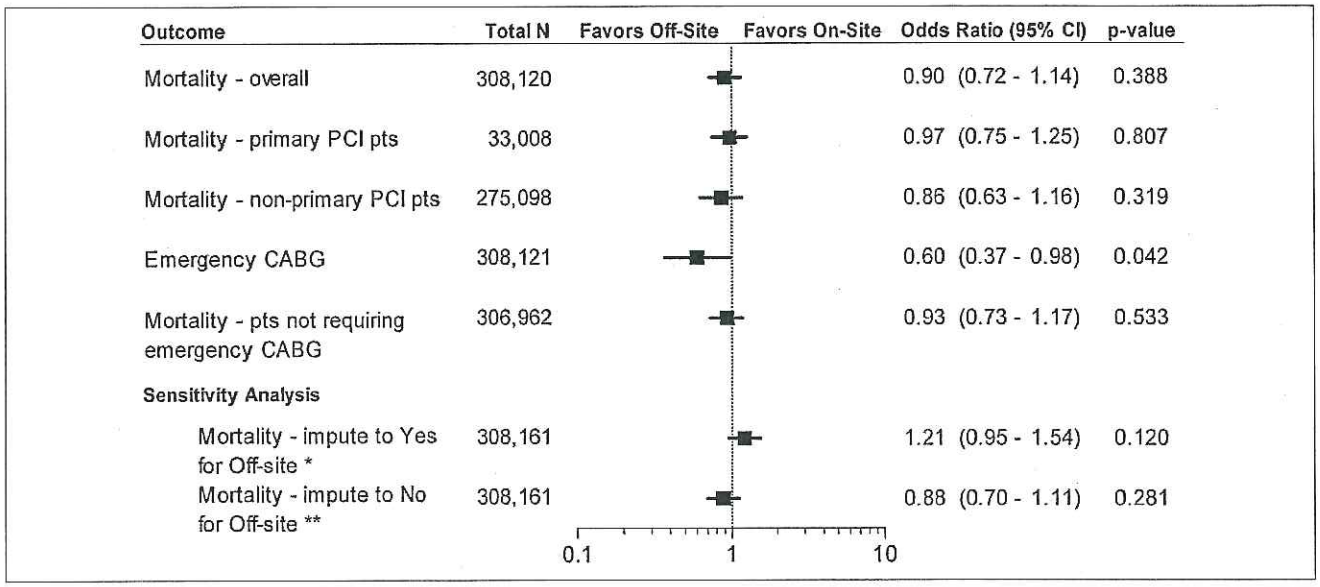
Conversely, the 1.5-fold higher risk-adjusted incidence of emergency surgery at on-site PCI centers could reflect a lower threshold to opt for emergency surgery if there is any doubt about a suboptimal result, as surgery is available without the added logistics of transfer. An alternative explanation could be that on-site centers perform higher risk elective cases, as is suggested by the clinical and lesion characteristics profiles in this study. In addition, it is possible that patients may have had initial angiography at off-site facilities, found to have complex coronary anatomy and/or high-risk MI subsets with a higher predisposition to emergency surgery, then deferred and transferred to an on-site center for PCI. These complicated potential scenarios and the detailed reasons for case selection were beyond the scope of the NCDR database elements. Regardless, the increased risk-adjusted incidence of emergency surgery at on-site PCI programs did not translate into an increase in mortality.

Data from the Capabilities Survey revealed a mean transit time of 25 ± 17 min from off-site facilities. The British Cardiovascular Interventional Society has recommended a 90 min to emergency surgery standard (29).

JACC Vol. 54, No. 1, 2009
June 30, 2009:16–24

Figure 2 Risk-Adjusted Analysis of Outcomes

Odds ratio plot of risk-adjusted outcomes, including sensitivity analysis for missing mortality data. Odds ratio: outcomes for patients at off-site (vs. on-site) facilities, adjusting for within site correlations and potential confounding variables. *Worst case scenario: all patients with missing mortality data were considered to have died. **Best case scenario: all patients with missing mortality data were considered as alive. CABG = coronary artery bypass graft surgery; CI = confidence interval; PCI = percutaneous coronary intervention; pts = patients.



This includes not only the transit time, but also the total time from the initial decision to transport (including call time, transfer of patient from catheterization laboratory to vehicle, vehicle to operating suite), to the actual time of initiating cardiopulmonary bypass at the receiving surgical center. The transit time in the NCDR survey was an estimate of basic travel time and did not include the above additional time elements. However, based on the transit time, most off-site PCI programs in our study may be able to meet this global standard of 90 min by having a clear decision process and heightened logistical coordination with ambulance services and the receiving surgical center.

The demographics of the off-site centers in our study suggests these facilities conform to the stated goals of lowering geographic barriers and facilitating access to PCI, particularly for those patients presenting with STEMI (5,6). The Capabilities Survey also indicates these programs are well staffed and organized with good logistical plans. The fact that 81% of the off-site center operators rotated to an on-site PCI center suggests that most of the off-site facilities were hub-and-spoke centers staffed by large group practices. Overall, the information suggests that the off-site PCI programs in this study have demonstrated a strong commitment to the classic Donabedian triad of structure, process, and outcomes measurements (30).

Study limitations. First, this study is subject to the usual concerns regarding observational registry data. There may be an inherent bias in off-site PCI programs that are either mandated by regulatory agencies or choose on their own to participate in the NCDR. Participants in any registry may be prone to "game" the system, particularly if score carding and public disclosure is an issue.

Second, this study includes outcomes up to the time of hospital discharge. Data regarding long-term outcomes are not currently captured in the NCDR CathPCI Registry. In addition, outcomes are assessed and analyzed on an institutional level, not on an individual operator level.

Third, specific in-depth details regarding clinical presentation, case selection, procedural complications, morbidity, and mortality were sometimes beyond the purview of the basic datasets. However, a special data clarification effort was utilized to resolve the 172 of 8,736 off-site patients (2%) for whom mortality or transfer data were questioned, resulting in clarification of 154 of these patients (90%), leaving 18 of 8,736 (0.2%) not clarified. A sensitivity analysis confirmed that the unclarified data would not have affected the risk-adjusted mortality analysis results.

Fourth, although this NCDR study indicates that nonprimary PCI can be done safely at off-site facilities, the efficacy of truly elective PCI at off-site facilities can perhaps be best addressed by a large randomized prospective trial such as the C-PORT (Cardiovascular Patient Outcome Research Team) Elective Angioplasty Study, which is under way. However, such studies are difficult to conduct, and results may not be forthcoming for some time. In the interim, a comprehensive large database such as the NCDR CathPCI Registry offers a realistic and

relative contemporary quality assurance standard to monitor these issues. Based on the experiences gained with this current study, the NCDR plans to sponsor a proactive comprehensive working group of off-site PCI centers to further communicate and track outcomes. This effort will coincide with the upcoming transition to the next CathPCI database version 4.0.

Finally, a participation bias cannot be excluded. The total number of PCI centers in the U.S. that do not have surgery on site is not definitively known (22) but may number ≈250. Of these, it is estimated that one-third submit data to another peer-reviewed registry, a spoke and hub partner database, or a multicenter trial. Thus, the 60 off-site PCI facilities in this NCDR study may represent a minority of such programs in the nation and are probably in the upper tier of quality. With this perspective, the results reported here may not be applicable to all PCI centers without surgical backup on site, particularly those that do not participate in any formal data registry or clinical trial.

Conclusions

Compared with on-site PCI centers, off-site PCI programs in the NCDR were predominantly located in nonurban areas, had lower annual PCI volume, treated a higher percentage of patients who presented with subsets of MI, and had better reperfusion times in primary PCI. Off-site PCI centers had similar observed procedure success, morbidity, emergency cardiac surgery rates, and mortality in cases that required emergency surgery. The risk-adjusted mortality rates in off-site PCI facilities were comparable to those of PCI centers that had cardiac surgery on site, regardless of whether PCI was performed as primary therapy for STEMI or in a nonprimary setting.

These findings should not be extrapolated to encourage the widespread proliferation of more PCI programs without surgery on site to fulfill a political or an economic agenda. Rather, our study does confirm the safety of an off-site strategy at PCI centers where rigorous clinical, operator, and institutional criteria are in place and where data are submitted and reviewed in a comprehensive multicenter registry such as the NCDR.

Acknowledgments

The authors would like to thank Jessica Morris, MBA, and Kristi Mitchell, MA, MPH, of the NCDR for their tireless work and outstanding efforts in the conduct of the data clarification project. Tammy Davis and Susan Queen of Wake Forest University School of Medicine deserve special thanks for their expertise in the preparation of this paper.

EXECUTIVE SUMMARY

- Cardiovascular diseases (CVD) are a great public health concern. CVD account for about one-third of all Connecticut resident deaths. Coronary heart disease (CHD), cerebrovascular disease (stroke) and heart failure (HF) are the main types, accounting for 48%, 15%, and 8% respectively of all CVD deaths.

- The CVD, CHD, and stroke age-adjusted mortality rates of Connecticut residents decreased significantly between 1999 and 2008.

- Approximately 55% of all Connecticut resident CVD deaths are among females. However, males have significantly higher age-adjusted CVD mortality rates (2006-2008 data).

- Black Connecticut residents have the highest age-adjusted CVD mortality rate as well as higher age-adjusted CVD, CHD, and stroke premature mortality rates compared with White and Hispanic residents (2006-2008 data).

- Hispanic Connecticut residents have significantly lower age-adjusted CVD and CHD mortality rates than White residents (2006-2008 data).

- About 18% of all hospital discharges in Connecticut are due to CVD. Approximately 26% of CVD hospitalizations are due to CHD, 12% to stroke, and 18% to HF (2008 data).

- Connecticut male residents have higher age-adjusted rates of hospitalizations for CVD, CHD, stroke, and HF than female residents. Black Connecticut residents have higher rates of hospitalizations for CVD, stroke, and HF than White and Hispanic residents (2008 data).

- About $2.2 billion was billed for CVD hospitalizations in Connecticut in 2008. Approximately 34% of CVD charges are for CHD, 12% for stroke, and 12% for HF. CVD also incur enormous indirect costs.

- Risk factors for CVD may be modifiable or non-modifiable. Key modifiable risk factors are high blood pressure, high blood cholesterol, smoking, diabetes, obesity, and physical inactivity. Non-modifiable risk factors include increasing age and family history of heart disease and stroke.

- High blood pressure (HBP) is a major risk factor for heart attack and stroke. About 27% of Connecticut adults have HBP. Connecticut males are more likely than females to have HBP. About 25% of White, 36% of Black, and 22% of Hispanic adults in Connecticut have HBP. Also, Connecticut adults with lower annual household incomes are more likely to have HBP compared to adults with higher annual household incomes (2007-2009 data).

- High blood cholesterol (HBC) is a major risk factor for CHD. About 38% of Connecticut adults have HBC. Connecticut males are more likely than females to have HBC. The prevalence of HBC increases with age. Black and Hispanic Connecticut adults are less likely than White adults to have had their blood cholesterol tested. Connecticut adults with lower annual household incomes are less likely than adults with higher annual household incomes to have had their blood cholesterol tested (2007-2009 data).

- Cigarette smoking increases the risk of heart attack, stroke, and death from CHD. About 16% of Connecticut adults are current smokers. Current adult smokers are more likely to be younger, have lower annual household incomes, and be less educated. Among adults, smoking rates do not vary significantly by gender or race and ethnicity (2007-2009 data). According the 2009 Connecticut School Health Survey, 15.3% of high school students are current smokers. White high school students are more likely than Black and Hispanic students to be current smokers.

- Diabetes has been recognized as a major risk factor for CVD. An estimated 6.9% of Connecticut adults have diagnosed diabetes. Connecticut males are more likely to have diabetes than females. Also, high rates of diabetes are associated with older age, lower socioeconomic position, and racial and ethnic minority status. About 5.6% of White, 14.9% of Black, and 10.5% of Hispanic adults in Connecticut have diabetes (2007-2009 data).

- Obesity is an independent risk factor for CVD. An estimated 10.4% of high school students in Connecticut are obese. High school males are more likely to be obese than females and Hispanic students are more likely to be obese than White and Black students (2009 data). Approximately 21% of Connecticut adults are obese. Older adults are more likely to be obese than younger adults; males are more likely to be obese than females; and those with lower annual household incomes are more likely to be obese than those with higher annual household incomes. Also, Black and Hispanic adults are more likely to be obese than White adults (2007-2009 data).

- Physical inactivity is associated with an increased risk of a number of chronic health conditions including CHD, high blood pressure, and obesity. Approximately 47% of Connecticut adults participate in less than the recommended amount of physical activity. Older adults, females, and adults with lower annual household incomes have higher rates of physical inactivity. About 44.5% of White, 59.7% of Black, and 54.2% of Hispanic Connecticut adults are physically inactive (2007-2009 data).

- The co-prevalence of risk factors places an individual at elevated risk for CHD and stroke. About 42% of Connecticut adults have two or more modifiable risk factors for CVD (2007-2009 data).

- Early recognition of the signs and symptoms of heart attack and stroke increase the likelihood of immediate emergency transport to the hospital and timely medical care. Only 13.6% of Connecticut adults can identify all the proper heart attack signs and only 22.6% can identify all the proper stroke signs. Women tend to be more knowledgeable than men about the signs and symptoms of heart attack and stroke (2007-2009 data).

- Access to health care is crucial to the prevention, treatment, and management of CVD. About 9% of adults in Connecticut do not have health insurance. Approximately 6% of White, 21% of Black, and 30% of Hispanic adults in Connecticut do not have health insurance (2007-2009).

- Targeted public health interventions are warranted for all Connecticut residents with multiple risk factors. Special emphasis should be placed on evidence-based interventions that address risk factor reduction among Black, Hispanic, and lower-income Connecticut adults.

THE BURDEN OF CARDIOVASCULAR DISEASES IN CONNECTICUT

INTRODUCTION

Cardiovascular disease refers to a wide variety of heart and blood vessel diseases. The most common forms of cardiovascular disease are coronary heart disease (CHD) and cerebrovascular disease. Essential hypertension, heart failure (HF), and atherosclerosis are other common cardiovascular diseases (CVD).[1] CVD are of great public health concern because more than one-third of all deaths in Connecticut are due to CVD and because prevention efforts have shown great potential in reducing the morbidity, mortality, and disability of CVD.[2, 3]

MORTALITY

CVD accounted for 9,351 Connecticut resident deaths in 2008, or about 33% of all deaths for the period. In contrast, cancer deaths accounted for 24%; chronic lower respiratory disease, 5%; unintentional injuries, 5%; and diabetes, 2% of all Connecticut resident deaths (Table 1).[3]

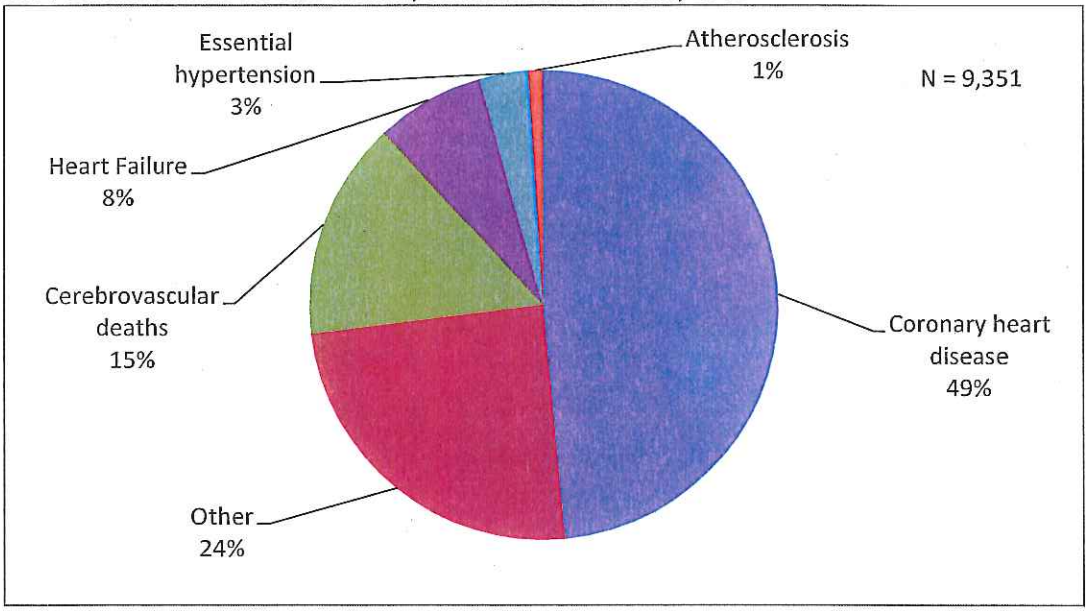
Table 1. Connecticut Resident Deaths, 2008

Cause of Death	Number of Deaths	Percent of Deaths
All Causes	28,749	100%
Cardiovascular Disease	9,351	33%
Cancer	6,765	24%
Chronic Lower Respiratory Disease	1,494	5%
Unintentional Injury	1,362	5%
Alzheimer's Disease	831	3%
Pneumonia and Influenza	688	2%
Diabetes	618	2%

Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

The major CVD are CHD and cerebrovascular disease or "stroke". Stroke is the most severe clinical manifestation of cerebrovascular disease, and the terms are used interchangeably in this report.[4] CHD accounts for 49% of all CVD deaths and includes hypertensive heart disease and ischemic heart disease (2008 data). Stroke is responsible for about 15% of CVD deaths in Connecticut, and includes two major types - ischemic stroke and hemorrhagic stroke. HF accounts for 8% of all CVD deaths, while essential hypertension and atherosclerosis account for 4% of all CVD deaths in Connecticut (Figure 1).[3]

Figure 1. Cardiovascular Disease Deaths, Connecticut Residents, 2008

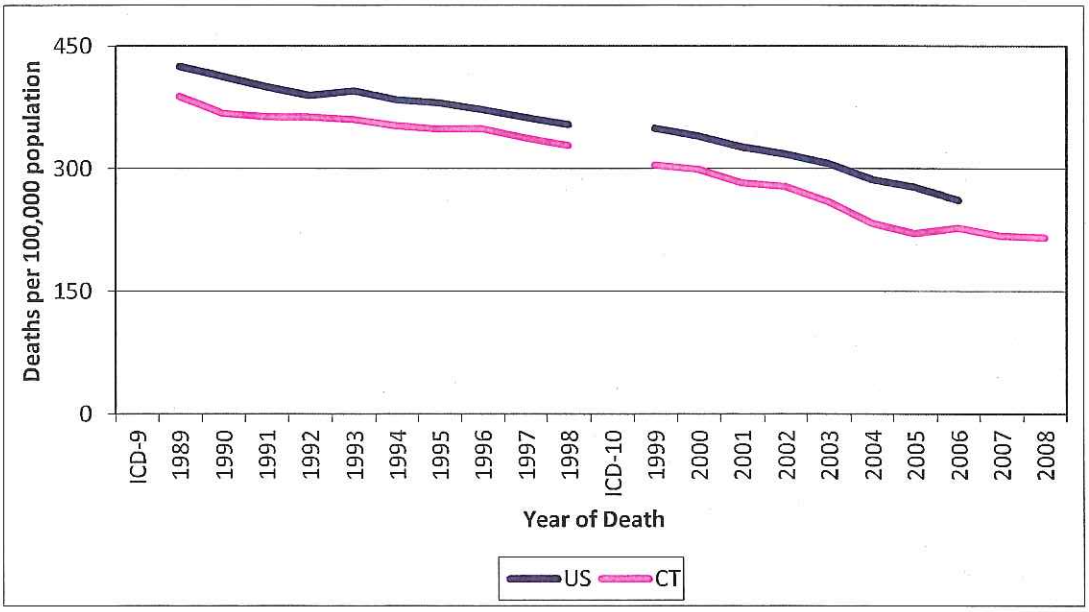


Sources: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Trends in Age-adjusted Mortality

Since the 1990s, CVD and CHD mortality rates* have decreased significantly for all Connecticut residents.[5, 6] This continuing decrease in Connecticut CVD and CHD mortality rates mirrors a similar decline in CVD and CHD mortality rates nationwide.[7] CVD and CHD mortality rates for Connecticut residents have been consistently lower than those for the United States population (Figure 2 and Figure 3).[3, 7] Since 2001, the Connecticut resident CHD mortality rate has been below the *Healthy People 2010* target of 166 per 100,000 population (Figure 3). There is no *Healthy People 2010* target for CVD.[8]

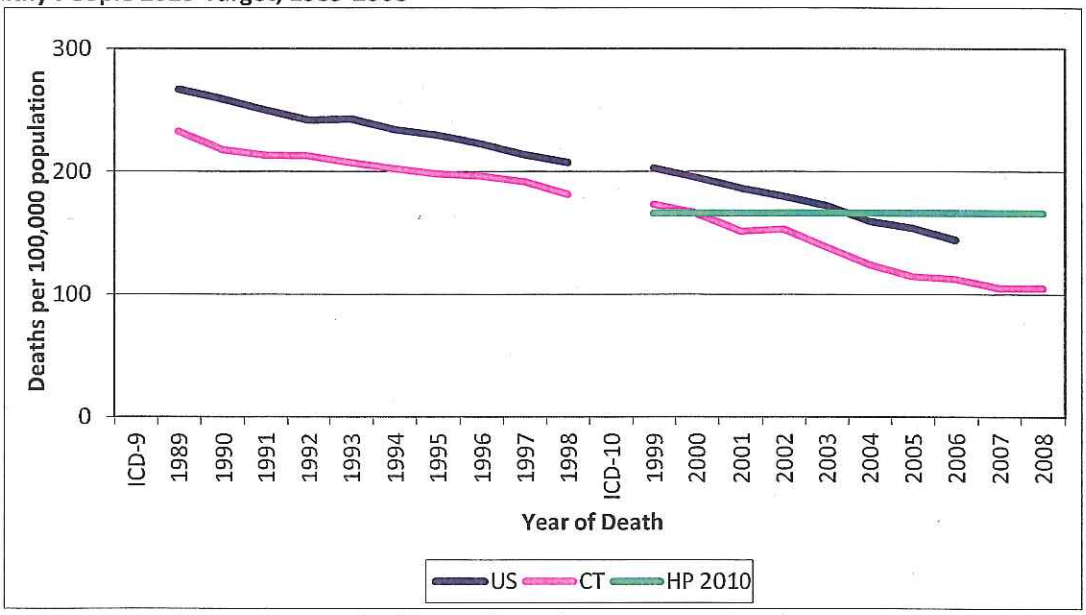
Figure 2. Age-adjusted Mortality Rates for Cardiovascular Disease, Connecticut & United States, 1989-2008



Sources: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 codes: 390-459.9 (1989 to 1998); ICD-10 codes: I00-I78.9 (1999 to 2008).

* The mortality rates presented in this report are age-adjusted mortality rates (AAMR). The AAMRs were computed by the direct method using the 2000 U.S. standard million population. The AAMRs were calculated using the death records of Connecticut residents.

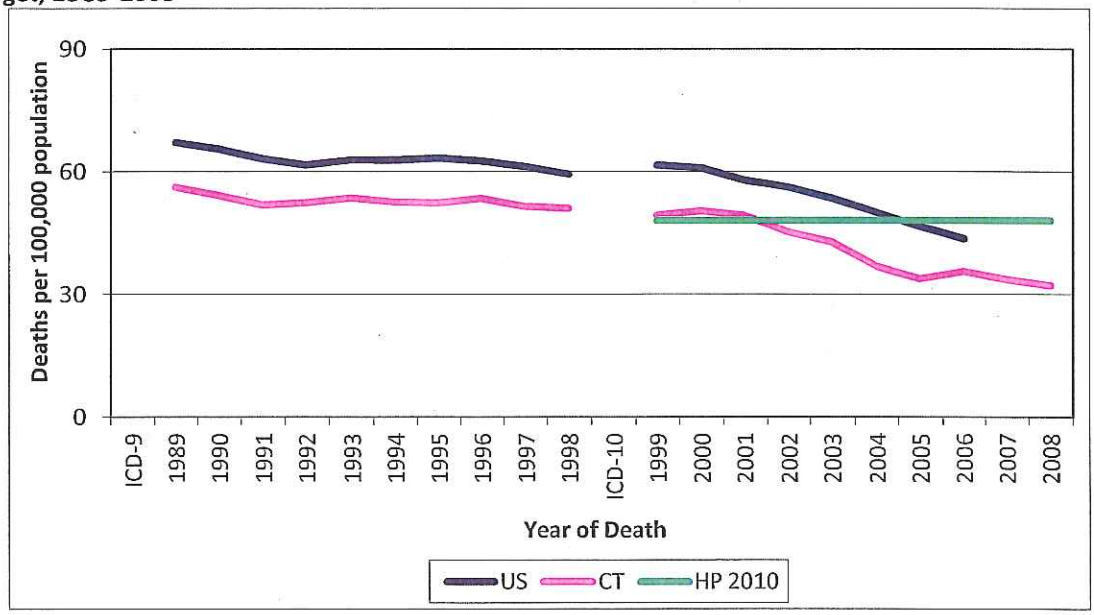
Figure 3. Age-adjusted Mortality rates for Coronary Heart Disease, Connecticut, United States, & Healthy People 2010 Target, 1989-2008



Source: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 codes: 402,410-414, 429.2 (1989 to 1998); ICD-10 codes: I11, I20-25 (1999 to 2008).

Stroke mortality rates of Connecticut residents did not change significantly in the 1990s.[5] However, decreasing trends have been observed since 1999.[6] Connecticut resident mortality rates from stroke have been consistently lower than those of the U.S.[7] Since 2002, the Connecticut resident stroke mortality rate has been below the *Healthy People 2010* target of 48 per 100,000 population (Figure 4).[3, 8]

Figure 4. Age-adjusted Mortality Rates for Stroke, Connecticut, United States, & Healthy People 2010 Target, 1989-2008

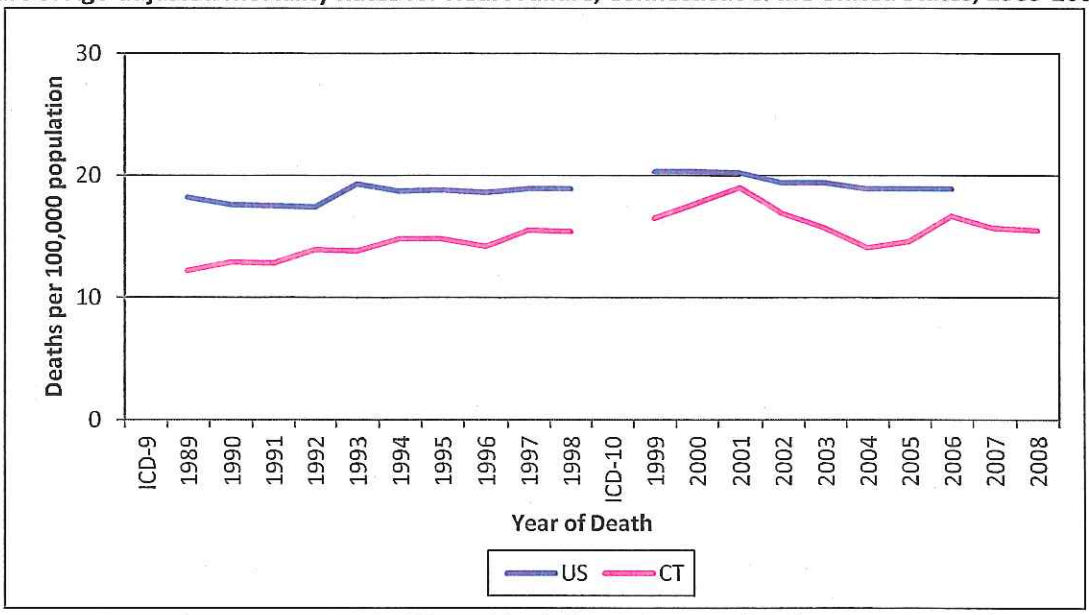


Sources: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 codes: 430-438 (1989 to 1998); ICD-10 codes: I60-69 (1999 to 2008).

During the 1990s, the Connecticut resident HF mortality rates increased significantly.[5] The increase in the HF mortality rates throughout the 1990s has been attributed to more people surviving heart attacks experienced earlier in life and to the aging population.[1] Approximately 60% of all HF deaths in Connecticut occur in persons aged 85 or older. In contrast, 45% of all CHD deaths and 49% of all cerebrovascular disease deaths occur in persons 85 and older.[7] The 2006-2008 Connecticut resident HF mortality rate was significantly lower than the 1999-2001 rate [data not shown]; however, linear trend analyses of HF mortality rates did not show a statistically significant change ($p \leq 0.05$) for the period 1999-2008.[3,6]

Connecticut HF mortality rates have been consistently lower than those of the U.S.[3,7] There is no *Healthy People 2010* target for HF (Figure 5).[8]

Figure 5. Age-adjusted Mortality Rates for Heart Failure, Connecticut & the United States, 1989-2008



Sources: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 code: 428.0 (1989 to 1998); ICD-10 code: 150.0 (1999 to 2008).

Mortality by Gender

Approximately 55% of all Connecticut resident CVD deaths are among females (2006-2008 data). While more females than males die from CVD in Connecticut, males have higher CVD mortality rates (Table 2). Connecticut males have a 45% higher mortality rate due to CVD compared with females, a 71% higher mortality rate due to CHD, and a 30% higher mortality rate due to HF ($p<0.001$ for all comparisons). The stroke mortality rates of Connecticut males and females do not differ significantly.[3]

Table 2. Cardiovascular Diseases Deaths and Age-adjusted Mortality Rates (AAMR) per 100,000 Population, Connecticut Residents, 2006-2008

Cause of Death	All		Male		Female	
	Deaths	AAMR	Deaths	AAMR	Deaths	AAMR
All Cardiovascular Diseases	28,369	219.7	12,889	266.8	15,480	184.4
Coronary Heart Disease	13,840	107.4	6,874	141.3	6,966	82.7
Stroke	4,385	33.8	1,646	34.5	2,739	32.6

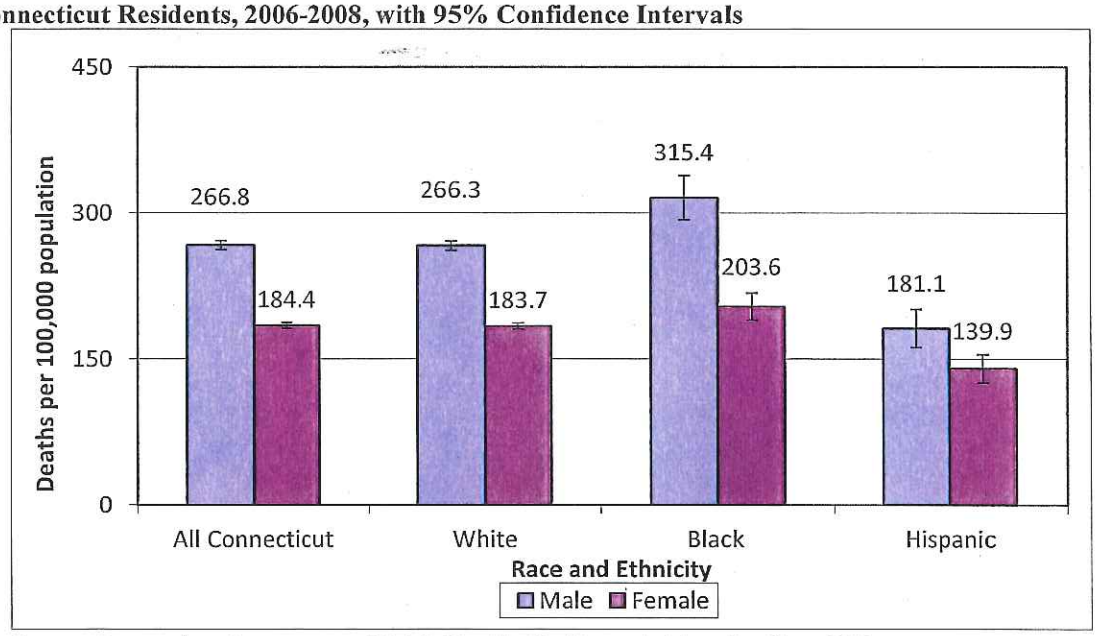
Mortality by Gender, Race and Ethnicity

Cardiovascular Disease

The Connecticut resident CVD mortality rates differ by gender, race and ethnicity[†] with Black Connecticut residents having the highest CVD mortality rates (2006-2008 data). The CVD mortality rates of Black males and females are significantly higher than those of White males ($p<0.001$) and females ($p<0.05$), respectively. Black males and females also have significantly higher CVD mortality rates compared with Hispanic males and females ($p<0.001$ for both comparisons).[3] Conversely, Hispanic males and females have significantly lower mortality rates due to CVD than White males and females ($p<0.001$ for both comparisons) [Figure 6].[3] CVD mortality rates declined significantly for all subpopulation groups between 1999-2001 and 2006-2008 ($p<0.001$ for White and Black males and females; $p<0.005$ for Hispanic males; $p<0.01$ for Hispanic females) [data not shown].[3]

Figure 6. Age-adjusted Mortality Rates for Cardiovascular Disease by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



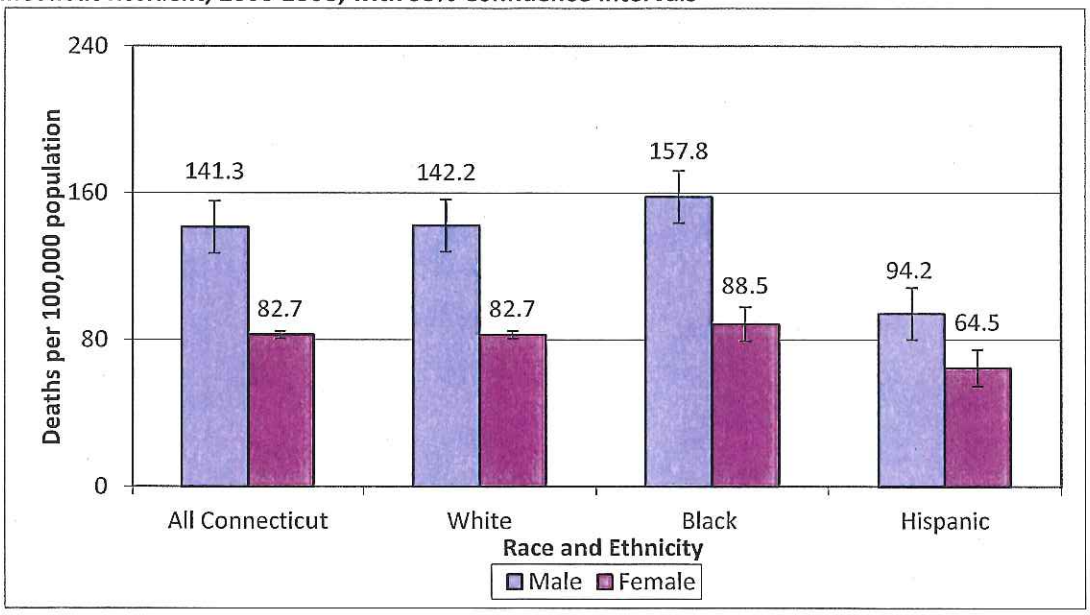
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

[†] Throughout this report racial groupings (e.g., "Black", "White") exclude persons of Hispanic ethnicity. A Hispanic ethnicity category is included in figures and tables reflecting data separate from race categories. Therefore, the modifier "non-Hispanic" is assumed.

Coronary Heart Disease

The CHD mortality rates differ somewhat by gender, race and ethnicity (2006-2008 data). Hispanic males and females have significantly lower CHD mortality rates than White males and females as well as Black males and females ($p < 0.001$ for males; $p<0.005$ for females) [Figure 7].[3] The CHD mortality rates of White males and females do not differ significantly from the rates of Black males and females (Figure 7).[3] CHD mortality rates declined significantly for all subpopulation groups in Connecticut between 1999-2001 and 2006-2008 ($p<0.01$ for Hispanic females; $p<0.001$ for other comparisons) [data not shown].[3]

Figure 7. Age-adjusted Mortality Rates for Coronary Heart Disease by Gender, Race and Ethnicity, Connecticut Resident, 2006-2008, with 95% Confidence Intervals

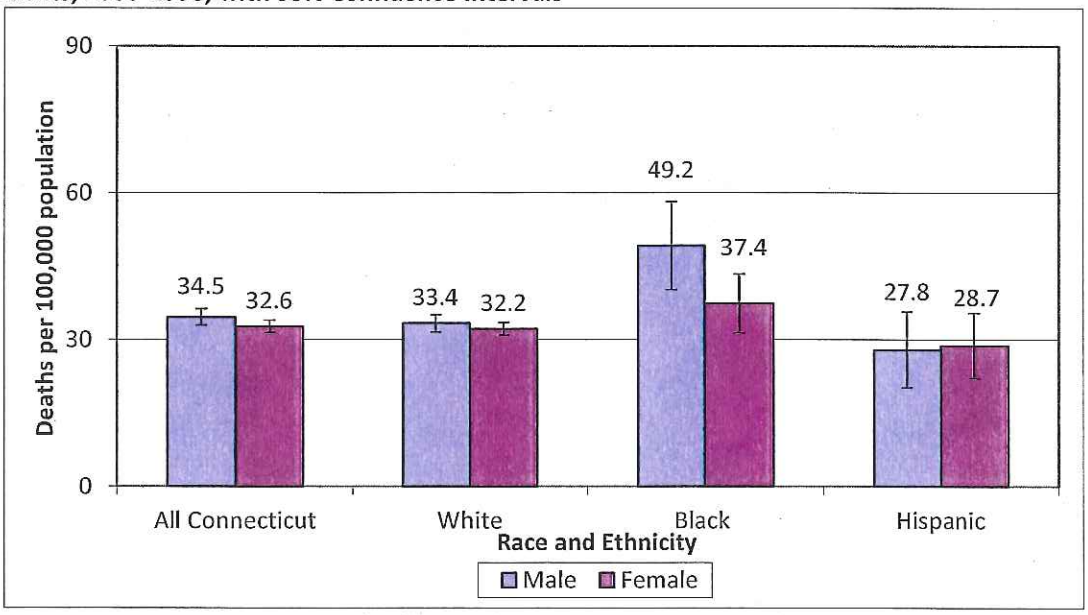


Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Stroke

Stroke mortality rates differ somewhat by gender, race and ethnicity (2006-2008). Black males have a significantly higher stroke mortality rate than White ($p<0.005$) and Hispanic males ($p<0.05$) [Figure 8].[3] However, the stroke mortality rates for Hispanic and White males do not differ significantly.[3] Likewise, the stroke mortality rates for White, Black, and Hispanic females do not differ significantly (Figure 8).[3] Stroke mortality rates declined significantly for White males ($p<0.001$), White females ($p<0.001$) and Black females ($p<0.005$) between 1999-2001 and 2006-2008 [data not shown].[3]

Figure 8. Age-adjusted Mortality Rates for Stroke by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals

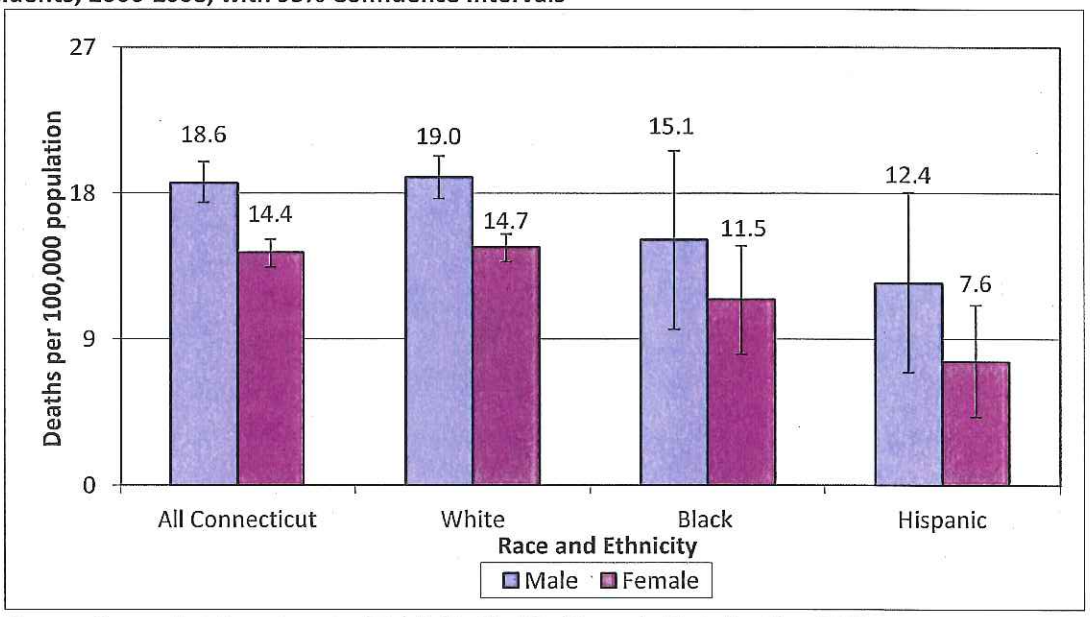


Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Heart failure

HF mortality rates vary little by gender, race and ethnicity (2006-2008 data). While the HF mortality rate of White females is significantly higher than the rate of Hispanic females ($p<0.005$), the HF mortality rate of White and Black females does not differ significantly [Figure 9].[3] The difference in the mortality rates of Black and Hispanic females does not reach statistical significance.[3] Also, the HF mortality rates of White, Black, and Hispanic males do not differ significantly [Figure 9].[3] White females and the overall Black Connecticut population experienced a statistically significant decline in the HF mortality rate between 1999-2001 and 2006-2008 ($p<0.05$ for both comparisons) [data not shown].[3]

Figure 9. Age-adjusted Mortality Rates for Heart Failure by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Premature Mortality by Gender, Race and Ethnicity

Premature mortality[‡], defined as the "years of potential life lost before age 75," focuses on deaths that occur at younger ages. For example, a person who dies at age 45 is considered to have lost 30 years of life, and a person who dies at 70 is considered to have lost 5 years of life.[9] Premature mortality is important because it emphasizes the years of productive life that are lost to society.

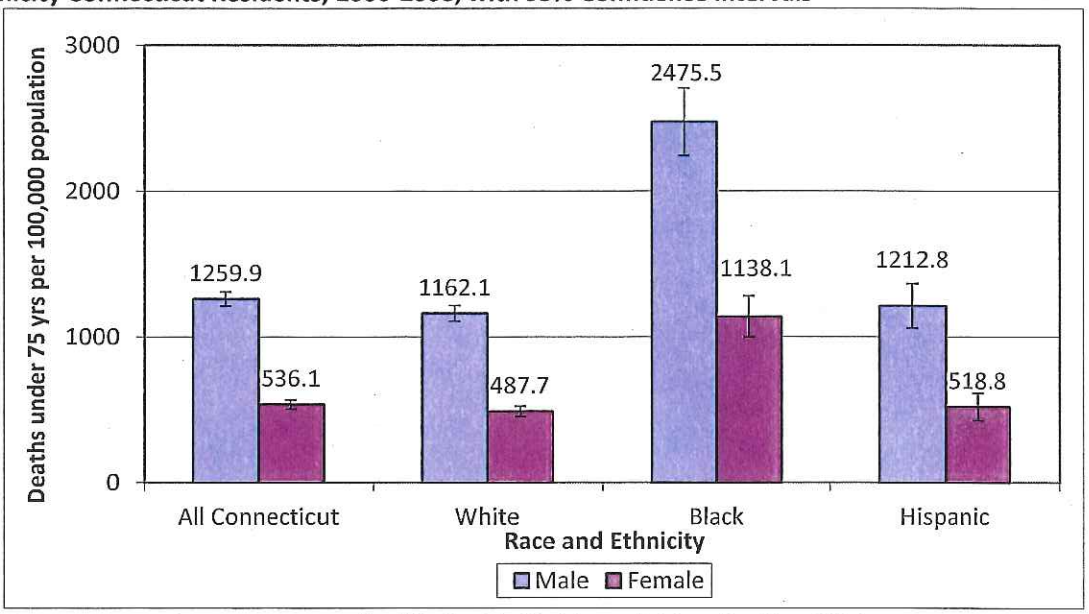
Cardiovascular Disease

CVD premature mortality rates differ by race and ethnicity as well as gender (2006-2008 data). Black males and females have significantly higher CVD premature mortality rates compared with White and Hispanic males and females ($p < 0.001$ for all comparisons) [Figure 10].[3] However, the CVD premature mortality rates of White males and females do not differ significantly from the rates of Hispanic males and females.[3] Also, males have significantly higher CVD premature mortality rates than females ($p<0.001$) (Figure 10).[3]

The CVD premature mortality rate declined significantly for the overall Connecticut population between 1999-2001 and 2006-2008 ($p<0.001$) [data not shown]. Similarly, CVD premature mortality rates declined significantly for White males ($p<0.001$), White females ($p<0.001$), Black females ($p<0.001$), Hispanic males ($p<0.05$), and Hispanic females ($p<0.05$) [data not shown]. CVD premature mortality rates for Black males did not change significantly from 1999-2001 to 2006-2008 [data not shown].[3]

[‡] The premature mortality rates presented in this report are age-adjusted "Years of Potential Life Lost (YPLL) under 75 years". Age-adjusted rates were computed by the direct method using the 2000 U.S. standard million population and Connecticut resident death records.

Figure 10. Age-adjusted Premature Mortality Rates for Cardiovascular Disease by Gender, Race and Ethnicity Connecticut Residents, 2006-2008, with 95% Confidence Intervals



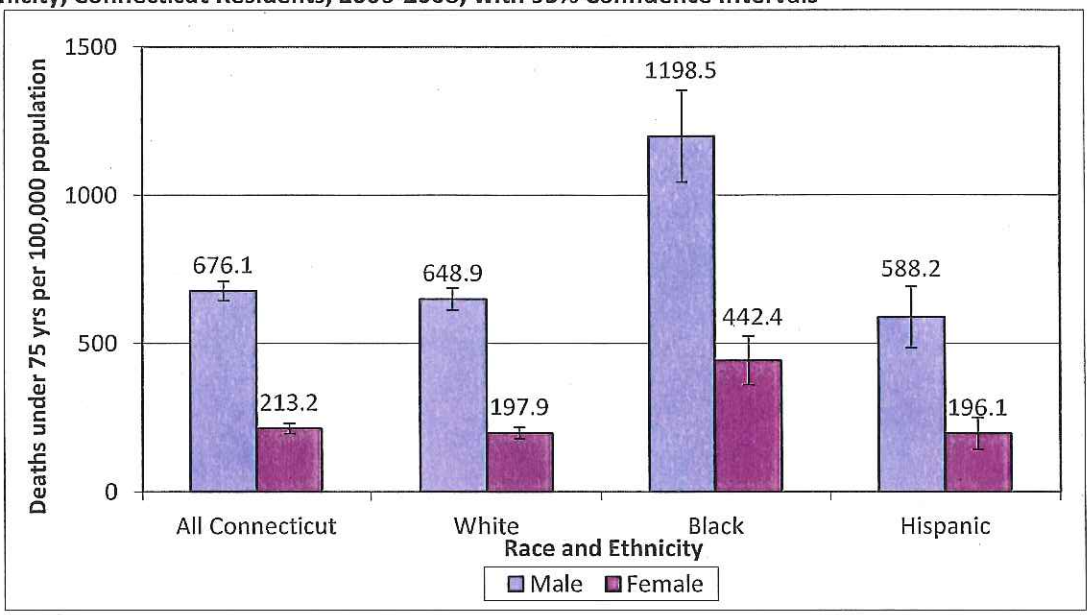
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Coronary Heart Disease

CHD premature mortality rates differ by race, ethnicity, and gender (2006-2008 data). The CHD premature mortality rates of Black males and females are significantly higher than those of White and Hispanic males and females ($p<0.001$ for all comparisons) [Figure 11].[3] However, the CHD premature mortality rates of White and Hispanic residents do not differ significantly.[3] Also, males have a significantly higher CHD premature mortality rate than females ($p<0.001$) [Figure 11].[3]

The CHD premature mortality rate declined significantly for the overall Connecticut population between 1999-2001 and 2006-2008 ($p<0.001$) [data not shown]. Similarly, CHD premature mortality rates declined significantly for all subpopulation groups (White males, $p<0.001$; White females $p<0.001$; Black males, $p<0.05$; Black females, $p<0.001$; Hispanic males, $p<0.005$; and Hispanic females, $p<0.05$) [data not shown].[3]

Figure 11. Age-adjusted Premature Mortality Rates for Coronary Heart Disease by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



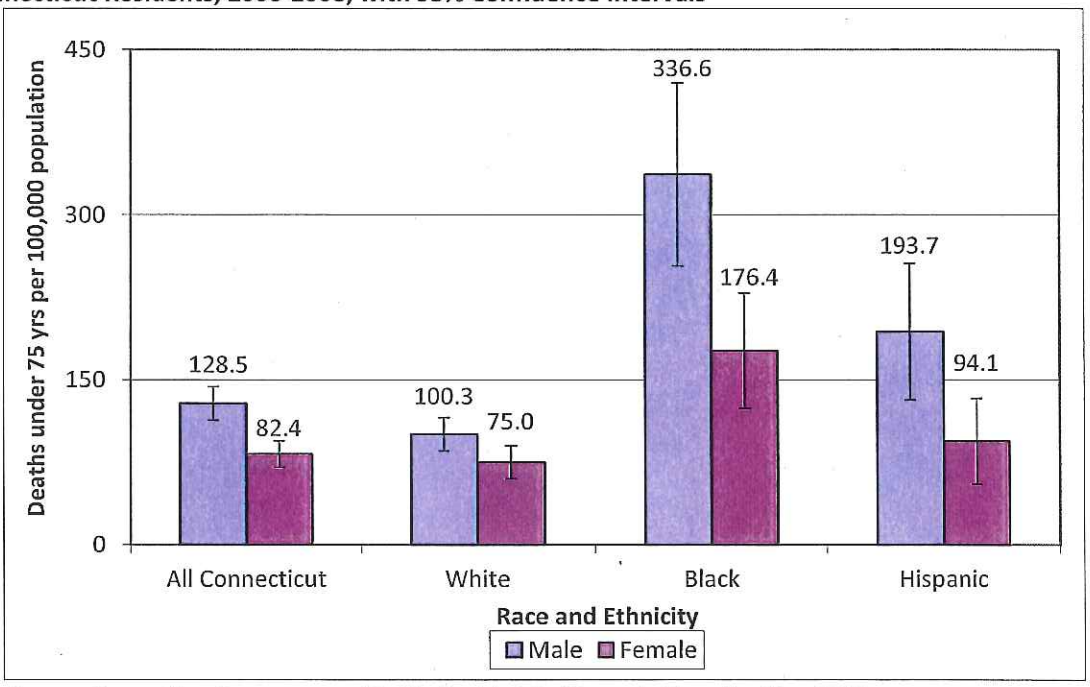
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Stroke

Stroke premature mortality rates vary by gender, race and ethnicity (2006-2008 data). Overall, males have a significantly higher stroke premature mortality rate than females ($p<0.005$) [Figure 12].[3] The stroke premature mortality rates of Black and Hispanic males are significantly higher than that of White males ($p<0.001$ for Black and White male comparison; $p<0.05$ for Hispanic and White male comparison) [Figure 12].[3] However, the stroke premature mortality rates of Hispanic and Black males do not differ significantly.[3] While Black females have a significantly higher stroke premature mortality rate than White females ($p<0.005$), the stroke premature mortality rates of Hispanic and White females are not statistically different [Figure 12].[3] Also, the stroke premature mortality rates of Black and Hispanic females do not differ significantly.[3]

The stroke premature mortality rate declined significantly for the overall Connecticut population ($p<0.005$), White males ($p<0.05$), and White females ($p<0.05$) between 1999-2001 and 2006-2008 ($p<0.005$) [data not shown]. The decline in the stroke premature mortality rates for Black and Hispanic males and females do not reach statistical significance (data not shown).[3]

Figure 12. Age-adjusted Premature Mortality Rates for Stroke by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Heart failure

The Connecticut resident HF premature mortality rate does not differ significantly by gender or race and ethnicity (Figure 13 and Figure 14) [2006-2008 data].[3] HF premature mortality rates did not decline significantly between 1999-2001 and 2006-2008 [data not shown].[3]

Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

MORBIDITY

There were 59,664 Connecticut resident discharges from Connecticut hospitals for all CVD in 2008. This represents 18% of all hospital discharges (excluding pregnancy and childbirth related discharges) and 23% of all hospital billing charges in the state.[10] Approximately 26% of all CVD discharges are due to CHD, 12% are for stroke, and 18% are for HF. The median length of stay for CHD, stroke, and HF is two, three, and four days, respectively. The median length of stay for all hospital discharges in Connecticut is three days.[10]

Hospitalizations by Gender

Hospitalization rates[§] vary by gender (2008 data). Males have significantly higher rates of hospitalizations for all CVD, CHD, stroke, and HF compared with females ($p < 0.001$). More females than males, however, are hospitalized for stroke and HF [Table 3].[10]

Table 3. Hospitalizations and Age-adjusted Hospitalization Rates (AAHR) for Cardiovascular Diseases per 100,000 Population, Connecticut Residents by Gender, 2008

Diagnostic Group	All		Male		Female	
	Discharges	AAHR	Discharges	AAHR	Discharges	AAHR
All Cardiovascular Diseases	59,664	1,483.1	31,748	1,862.9	27,916	1,184.1
Coronary Heart Disease	15,779	392.0	9,877	559.2	5,902	254.2
Stroke	7,413	183.6	3,626	216.1	3,787	158.1
Heart failure	10,725	259.9	5,331	326.8	5,394	213.8

[§]Hospitalization rates were calculated using 2008 Connecticut resident hospitalization discharge data and were age-adjusted based on the 2000 U.S. standard million population.

Hospitalization Rates by Race and Ethnicity

Hospitalization rates differ by race and ethnicity (2008 data). Black residents have significantly higher rates of hospitalizations for CVD, stroke, and HF than both White and Hispanic residents ($p<0.001$ for all comparisons). Black residents' rate of hospitalizations for CHD, however, is not significantly different than that of White and Hispanic residents.[10] Hispanic residents have significantly higher hospitalization rates for CVD ($p<0.001$) and CHD ($p<0.01$) than White residents. In contrast, Hispanic residents have a significantly lower rate of hospitalization for HF compared with White residents ($p<0.05$). Furthermore, the rates of hospitalization for stroke of Hispanic and White residents are not significantly different (Table 4).[10]

Table 4. Hospitalizations and Age-adjusted Hospitalization Rates (AAHR) for Cardiovascular Diseases per 100,000 Population, Connecticut Residents by Race and Ethnicity, 2008

Diagnostic Group	All		White, non-Hispanic		Black, non-Hispanic		Hispanic	
	Discharges	AAHR	Discharges	AAHR	Discharges	AAHR	Discharges	AAHR
All Cardiovascular Diseases	59,664	1,483.1	48,395	1,380.4	5,555	2,114.2	3,667	1,713.6

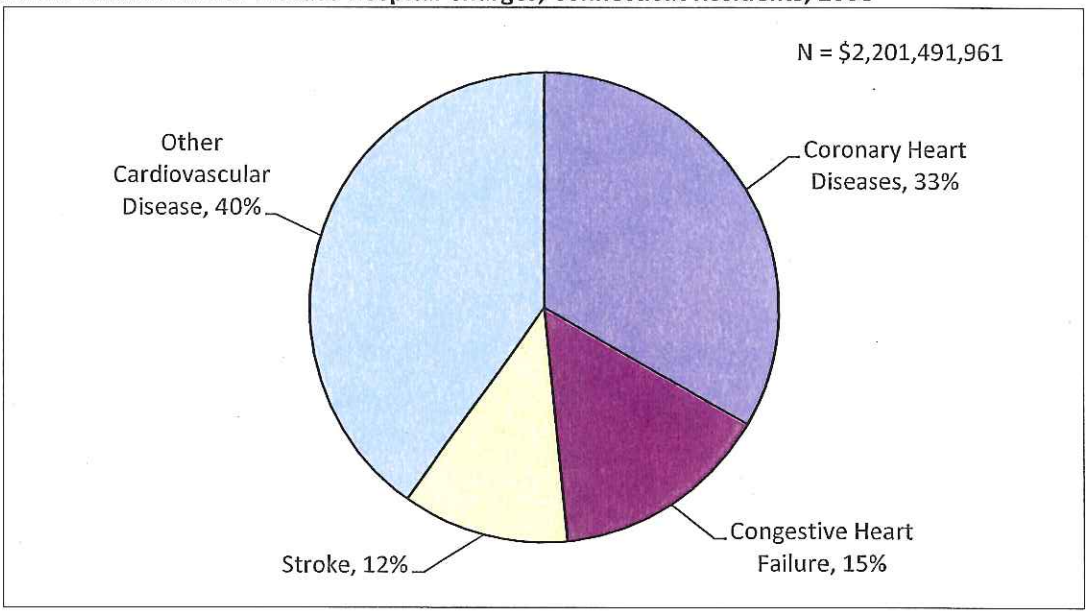
Source: Connecticut Department of Public Health, Connecticut Hospital Discharge Abstract and Billing Data Base, 2010.

Economic Costs

The estimated national annual cost for the medical management of CVD was $503.2 billion in 2010, or about $1600 per person.[2] This estimate includes direct medical costs and indirect costs. The indirect cost of CVD is associated with lost productivity from illness and premature death. Also, CVD are major causes of disability, limiting an individual's ability to live independently and negatively impacting the quality of life for individuals and families. For these reasons, CVD can incur enormous indirect costs. Assuming that disease rates and per person costs are the same in Connecticut as they are nationwide, the estimated economic burden of CVD in the state is about $5.8 billion. A large portion of these costs is attributable to inpatient hospitalizations.

Total Connecticut CVD hospital charges in 2008 were about $2.2 billion, with a median charge of $23,172 (Figure 15). About 33% of total CVD hospitalization charges were for CHD, 12% were for stroke, and 15% were for HF.[10] Median hospital charges were $34,792 for CHD, $19,772 for stroke, and $17,408 for HF. In contrast, the median charge for all hospital discharges in Connecticut was $16,727.[10]

Figure 15. Cardiovascular Disease Hospital Charges, Connecticut Residents, 2008



Source: Connecticut Department of Public Health, Connecticut Hospital Discharge Abstract and Billing Data Base, 2010.

RISK FACTORS

Risk factors for CVD may be non-modifiable (e.g., increasing age or family history) or modifiable (high blood pressure, high cholesterol, smoking, diabetes, obesity, physical inactivity) [Table 5]. Increasing age is a key risk factor for heart disease, stroke, and HF.[1] About 86% of all CVD deaths in Connecticut occur among those aged 65 years and older. About 85% of all CHD deaths, 90% of all stroke deaths, and 96% of all HF deaths in Connecticut occur among persons aged 65 years and older.[7] For men and women, major increases in the CVD mortality rate begin in the 35-to-44-year-old age group.[4] A family history of heart disease and stroke increases one's risk of developing these diseases. A combination of inherited characteristics and behavioral patterns (e.g. similar dietary, smoking, and activity habits) are thought to partially explain increased risk within families.[11]

Lower socioeconomic position (SEP) is an important risk marker for CVD. SEP is commonly measured by personal income, household income, or educational attainment level. Persons of lower SEP have higher CVD morbidity and mortality than do middle- or upper-income persons. Behavioral risk factors such as smoking, hypertension, and obesity are more prevalent in persons of lower SEP and may explain some of the observed disparity; however, other factors, like neighborhood socioeconomic environment, appear to have effects on individuals' risk for CVD.[1] Low-income neighborhood environments may contribute to increased CVD risk and poorer health outcomes because of such factors like poorer air quality, fewer food choices, and lower quality and/or lack of public services. Persons with lower incomes tend to have less access to and/or less effectively use preventive health services that are important to the early detection and treatment of hypertension.[12] While low-socioeconomic position may be considered "modifiable" in the sense that people can move in and out of poverty during a lifetime or over generations, it is not usually within a given individual's control to change his or her social position or neighborhood environment.

Table 5. Risk Factors for Cardiovascular Disease

Modifiable Risk Factors	Non-Modifiable Risk Factors
• High blood pressure • High cholesterol • Smoking • Diabetes • Obesity • Physical inactivity	• Increasing age • Family history

Modifiable Risk Factors

Current Connecticut Behavioral Risk Factor Surveillance System (BRFSS)** data show that about one out of three Connecticut adults report having one modifiable risk factor for CVD.[14] Following are summaries of the six main risk factors (high blood pressure, high blood cholesterol, tobacco use, diabetes, obesity, and physical inactivity) for CVD.

High Blood Pressure

High blood pressure (HBP) is a major risk factor for heart attack and the most important modifiable risk factor for stroke. People with elevated blood pressure (≥140 mmHg systolic / 90 mmHg diastolic) are 2 to 4 times more likely to develop CHD as are people with normal blood pressure (<120 mmHg systolic / 80 mmHg diastolic).[1] Studies have found that individuals with a normal blood pressure have approximately half the lifetime risk of stroke compared to those with high blood pressure.[13]

Approximately 27% of Connecticut adults report having HBP (2007-2009 data) compared with about 29% of adults nationwide (2009 data) (Figure 16).[14, 15] The risks for hypertension-related CVD increase markedly with age, as does the prevalence of hypertension, and drug treatment for HBP.[13] For example, 15.4% of Connecticut adults aged 35-44 years report having HBP compared with 57.8% of Connecticut adults aged 65 years and older ($p<0.001$) [data not shown].[14]

The rates of HBP also differ by gender. Approximately 27.4% of Connecticut males have HBP compared with 22.5% of females ($p<0.001$) [data not shown].[14]

The prevalence of HBP varies by race and ethnicity. Black Connecticut adults are more likely to have HBP than White and Hispanic Connecticut adults ($p<0.001$ for both comparisons). The rates of HBP among White and Hispanics adults do not differ significantly. About 25% of White, 36% of Black, and 22% of Hispanic adults report that they were told they had hypertension (Figure 17).[14]

** Unless otherwise stated, the BRFSS data presented in this report are based on 2007-2009 survey responses from non-institutionalized Connecticut adults.

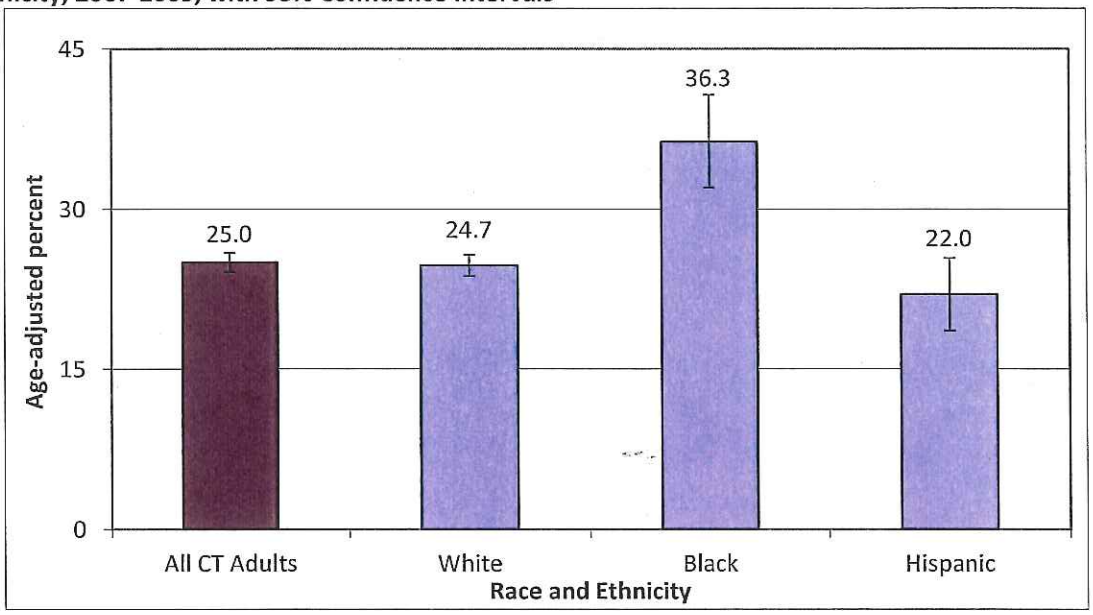
*Participated in less than the recommended amount of physical activity.

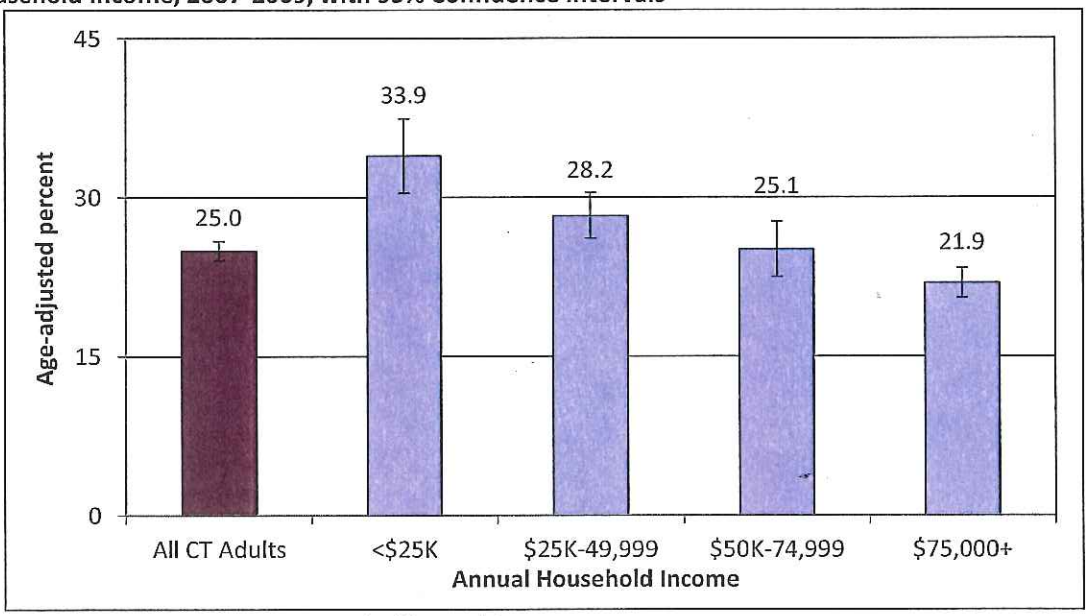
Figure 17. Age-adjusted Prevalence of High Blood Pressure among Connecticut Adults by Race and Ethnicity, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Connecticut adults with lower annual household incomes tend to have a higher prevalence of HBP compared to Connecticut adults with higher annual household incomes. For example, 33.9% of adults with an annual household income less than $25,000 have diagnosed HBP compared to 21.9% of adults with annual household income of at least $75,000 (p<0.001) [Figure 18].[14]

Figure 18. Age-adjusted Prevalence of High Blood Pressure among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

High Blood Cholesterol

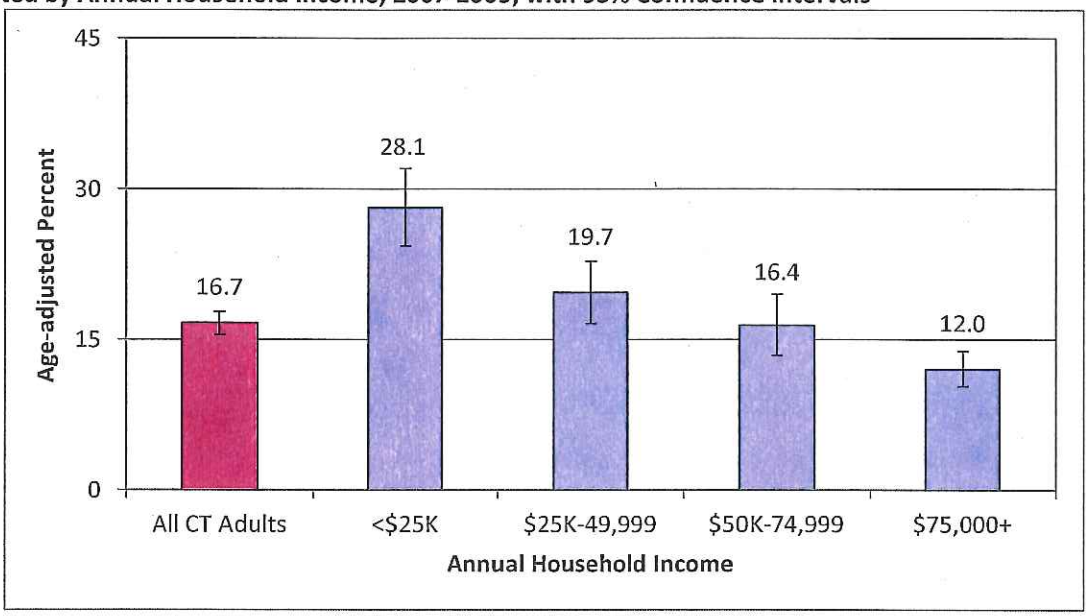
High blood cholesterol (HBC) is considered a major risk factor for CHD.[16, 17] Dyslipidemias, or an abnormal amount of lipids (e.g. high blood cholesterol) in the blood, were not traditionally regarded as a risk factor for stroke; however, a recent meta-analysis of statin therapy found that treatment of dyslipidemia decreases the risk of nonhemorrhagic stroke.[1] Control and reduction of HBC is important. A 10% decrease in total blood cholesterol levels may reduce the incidence of CHD by as much as 30%.[18]

About 38% of adults in Connecticut (2007-2009 data) and nationwide (2009 data) were told they had HBC (Figure 16).[14, 15] The prevalence of HBC increases with age. For example, 38.1% of Connecticut's adults aged 45-54 years report having HBC compared with 53.4% of Connecticut's adults aged 65 years and older ($p<0.001$) [data not shown].[14]

The prevalence of HBC also varies by gender. Approximately, 39.2% of Connecticut males have HBC compared with 29.7% of females ($p<0.001$) [data not shown]. [14]

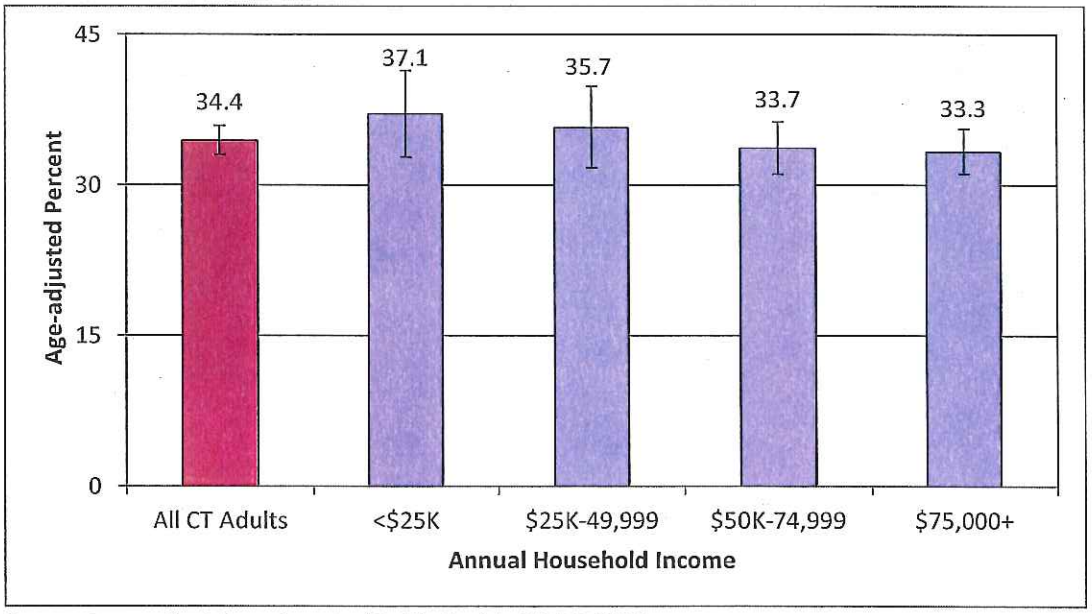
Connecticut adults compare favorably to adults nationwide in terms of cholesterol screening. About 82% of Connecticut adults report having had their blood cholesterol screened within the last five years (2007-2009 data) compared with 77% of adults in the U.S. (2009 data).[14, 15] Connecticut adults with lower incomes are more likely to report that they have never had their blood cholesterol tested compared to adults with higher incomes. For example, adults with annual household incomes less than $25,000 are significantly more likely to report that they have never had their blood cholesterol tested compared to individuals with annual household incomes of $75,000 or more ($p<0.001$) [Figure 19]. In contrast, the prevalence of HBC does not differ significantly by annual household income [Figure 20].[14]

Figure 19. Age-adjusted Percentage of Connecticut Adults Who Have Never Had Their Cholesterol Tested by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Figure 20. Age-adjusted Percentage of Connecticut Adults Who had Their Cholesterol Tested in the Past 5 Years and Were Told It was High by Annual Household Income, 2007-2009, with 95% Confidence Intervals

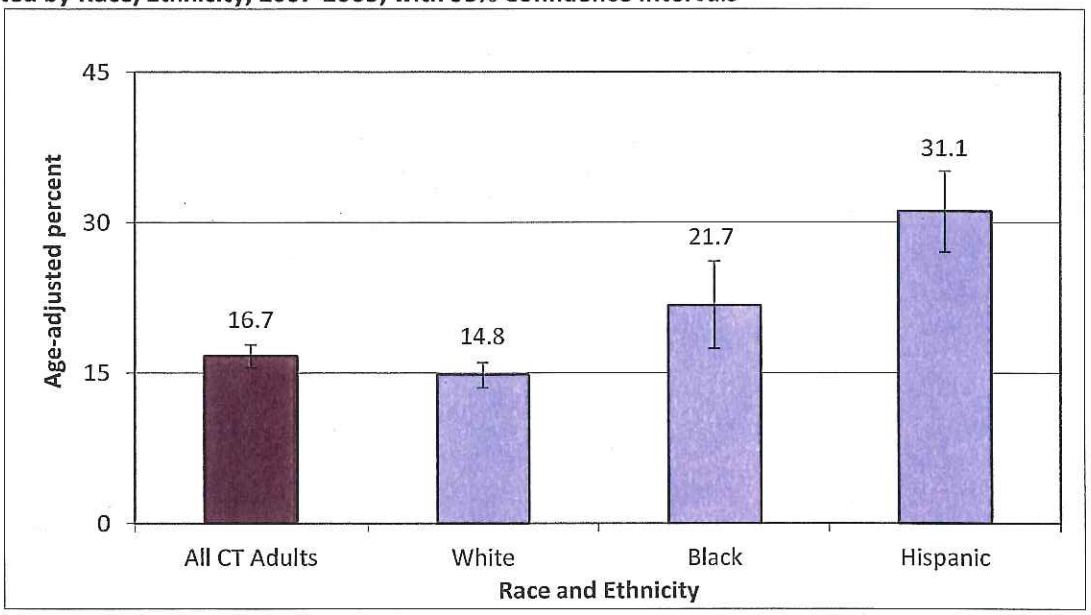


Source: Connecticut Department of Public Health, BRFSS, 2010.

Black and Hispanic adults are significantly more likely than White adults to report never having had their blood cholesterol tested ($p<0.05$ for Black and White comparison; $p<0.001$ for Hispanic and White comparison). Hispanic adults are also more likely than Black adults to report never having had their blood cholesterol tested ($p<0.05$). An estimated 14.8% of White, 21.7% of Black, and 31.1% of Hispanic adults report never having had their blood cholesterol tested [Figure 21]. In contrast, the prevalence of HBC does not differ significantly by race and ethnicity [data not shown].[14]

The rates of never having had blood cholesterol tested do not differ significantly by gender. Approximately, 16.9% of males and 16.4% of females in Connecticut have never had their blood cholesterol tested [data not shown].[14]

Figure 21. Age-adjusted Percentage of Connecticut Adults Who Have Never Had Their Cholesterol Tested by Race/Ethnicity, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Smoking

Cigarette smoking is a major modifiable risk factor for CVD. Smoking causes reduced blood vessel elasticity by increasing arterial wall stiffness. Smoking increases the risk of heart attack two-fold. Smokers have higher CHD mortality rates than non-smokers and the risk of death increases with greater number of cigarettes smoked. Current smokers have more than twice the risk of stroke compared with those who have never smoked. People who stop smoking decrease their stroke risk and their risk of CHD mortality.[1]

About 16% of Connecticut adults report being current smokers (2007-2009 data) compared with about 18% of adults nationwide (2009 data) [Figure 16].[14,15] According to the 2009 Connecticut School Health Survey (CSHS), 17.8% of high school students report being current smokers.[19]

Among adults, current smokers are more likely to be younger. For example, an estimated 22% of Connecticut adults aged 18 to 24 years old are current smokers compared with 14% of those aged 55 to 64 ($p<0.01$), and 6% of those aged 65 and older ($p<0.001$) [data not shown].[14] Smokers are also more likely to be individuals who have lower incomes and are less educated. For instance, about 31% of Connecticut's adults with annual household incomes under $25,000 are current smokers, compared to 10% of adults with annual household incomes of $75,000 or more ($p<0.001$) [Figure 22].[14] Similarly, about 31% of adults with less than a high school education report being current smokers compared to about 9% of adults who graduated from college ($p<0.001$) [data not shown].[14]

The rates of smoking do not differ significantly by gender. An estimated 16.8% of adult males and 15.2% of adult females are current smokers while an estimated 19.0% of high school males and 16.5% of high school females are current smokers (data not shown).[14,19]

Among Connecticut adults, smoking rates do not differ significantly by race and ethnicity. An estimated 15.8% of White, 19.1% of Black, and 15.6% Hispanic adults report being current smokers [data not shown].[14] However, the rates of smoking among high school students do vary by race and ethnicity. White Connecticut high school students are more likely to be current smokers than Black ($p<0.001$) and Hispanic ($p<0.05$) students. Also, Hispanic students are more likely than Black students to be current smokers ($p<0.05$) [Figure 23].[19]

Figure 22. Age-adjusted Percentage of Connecticut Adults Who Are Current Smokers by Annual Household Income, 2007-2009, with 95% Confidence Intervals

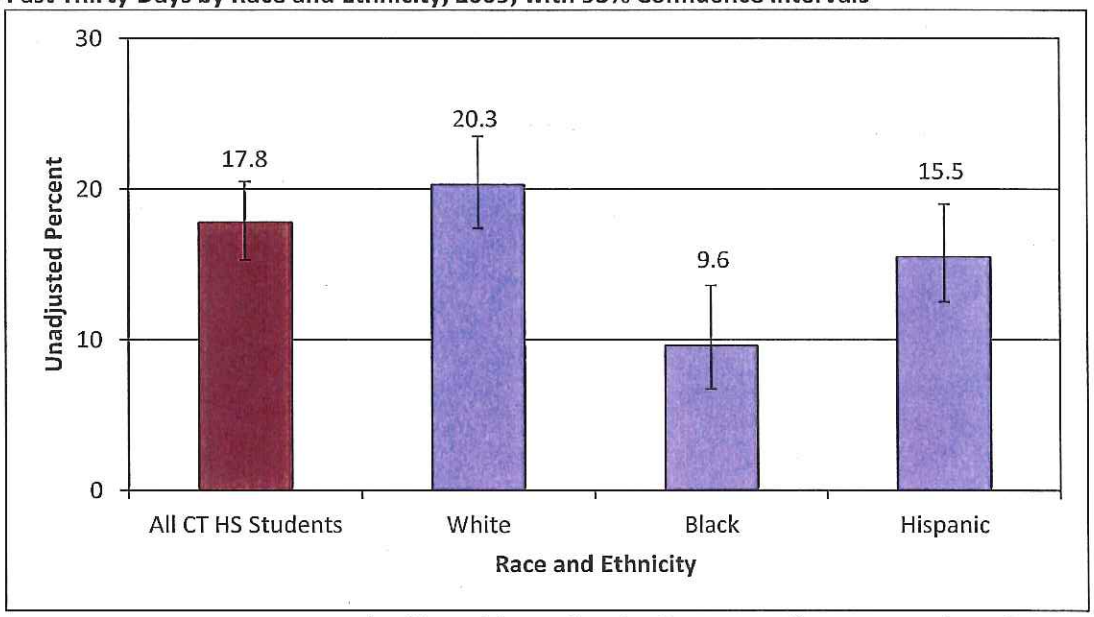
Figure 23. Percentage of Connecticut High School Students Who Smoked Cigarettes on One or More of the Past Thirty Days by Race and Ethnicity, 2009, with 95% Confidence Intervals



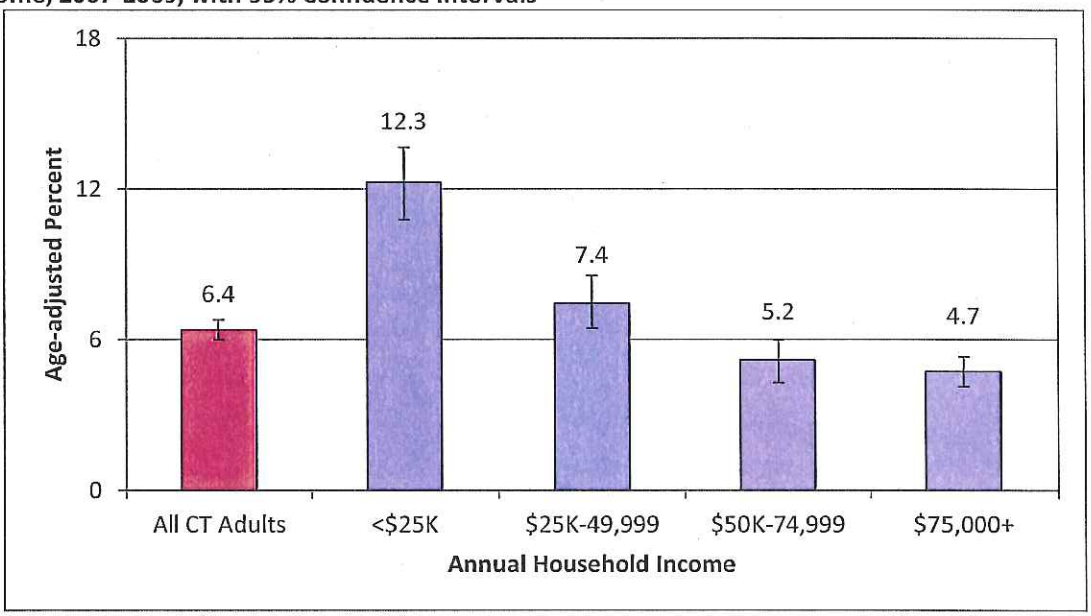
Source: Connecticut Department of Public Health, Youth Risk Behavior Surveillance System (YRBSS), 2010.

Diabetes

Diabetes has been recognized as a major risk factor for CVD. CVD is the primary cause of death for persons with diabetes, accounting for about 65% of the mortality. Individuals with diabetes are 2 to 4 times more likely to develop CHD and 2 to 5 times more likely to have a stroke than the rest of the population. People with diabetes often have HBP, HBC, and are overweight, further increasing their risk for CVD.[1]

An estimated 6.9% of Connecticut adults have diagnosed diabetes (2007-2009 data) compared with about 8% of adults nationwide (2009 data) [Figure 16].[14, 15] The prevalence of diabetes varies by gender, age, race and ethnicity, and SEP.[14, 20] Males are more likely to have diabetes than females. An estimated 7.3% of Connecticut males have diabetes compared with 5.7% of females ($p<0.005$) [data not shown].[14] Also, the prevalence of diabetes increases with age. Approximately 3% of adults aged 35-44 years report having diabetes compared to approximately 16.5% of adults aged 65 years and older ($p<0.001$) [data not shown].[14] Black and Hispanic adults have a significantly higher prevalence of diabetes compared with White adults ($p<0.001$ for both comparisons). The prevalence of diabetes among Black and Hispanic adults does not differ significantly. An estimated 5.6% of White, 14.9% of Black, and 10.5% of Hispanic adults report having diabetes [data not shown].[14] Adults with lower annual household incomes have a higher prevalence of diabetes compared to adults with higher annual household incomes. For example, approximately 12% of adults with annual household incomes under $25,000 report having diabetes, compared with about 5% of adults with household incomes over $75,000 ($p<0.001$) [Figure 24].[14]

Figure 24. Age-adjusted Prevalence of Diabetes among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Diabetes self-management education is essential because improperly controlled diabetes can result in CVD, kidney disease, blindness and loss of limb. It is, therefore, a particular concern that about 52% of Connecticut adults with diabetes report that they have never taken a course to manage the disease.[14]

Obesity

Body mass index (BMI), or weight adjusted for height, is a widely used screening method for obesity. For children and adolescents, BMI is compared to age- and gender-specific percentiles on the Centers for Disease Control and Prevention (CDC) growth charts. Children and adolescents with a BMI greater than or equal to the 85 percentile but less than the 95 percentile are considered overweight. Children and adolescents with a BMI greater than or equal to the 95 percentile are considered obese.[21] Medical guidelines for adults identify normal/desirable weight as a BMI under 25, overweight as a BMI of 25 to 29.9, and obese as a BMI of 30 or more. The prevalence of obesity has more than doubled over the past three decades in the United States.[21] The development of obesity involves social, behavioral, cultural, physiological, metabolic, and genetic factors. High calorie diets, along with less physical activity, have contributed to the obesity epidemic in our society.[21, 22]

Obesity increases the risk of morbidity from hypertension, dyslipidemia, CHD, and stroke. All-cause mortality increases with increasing body weight.[22] Obesity is also an independent risk factor for CVD. The risk of ischemic stroke increases with increasing BMI. Studies have also suggested that body fat distribution may affect CHD risk. Upper body or abdominal fat seems to increase CHD risk regardless of BMI. Weight reduction can affect several of the modifiable risk factors for stroke thereby reducing the incidence of stroke.[1]

According to responses to the 2009 CSHS, an estimated 14.5% of Connecticut high school students were overweight and 10.4% were obese.[19] Obesity rates among high school students in Connecticut vary by gender and race and ethnicity. Male Connecticut high school students are significantly more likely to be obese than female high school students ($p<0.05$). An estimated 13.8% of male and 6.7% of female high school students in Connecticut are obese [data not shown].[19] Also, Hispanic Connecticut high school students have higher rates of obesity than both White ($p<0.001$) and Black ($p<0.05$) high school students. The difference in the rate of obesity among White and Black high school students does not reach statistical significance. An estimated 8.7% of White, 12.5% of Black, and 17% of Hispanic Connecticut high school students are obese [data not shown].[19]

An estimated 21% of Connecticut adults are obese (2007-2009 data) compared with about 27% of adults nationwide (2009 data) [Figure 16].[14, 15] Approximately 38% of Connecticut adults are overweight and 41% are neither overweight nor obese [data not shown].[14] Rates of obesity differ by SEP. For example, approximately 30% of adults with annual household incomes less than $25,000 are obese compared with 17% of those with annual household incomes over $75,000 ($p<0.001$) [Figure 25].[14] Rates of obesity also differ by race and ethnicity. Black and Hispanic adults are more likely to be obese than White adults ($p<0.001$ for both comparisons) [data not shown]. Black adults are also more likely to be obese than Hispanic adults ($p<0.05$). About 20% of White, 36% of Black, and 27% of Hispanic adults are obese [data not shown].[14] Furthermore, males are more likely to be obese than females. An estimated 27.9% of males are obese compared with 19.2% of females ($p<0.005$) [data not shown].[14] Additionally, older adults are more likely to be obese than younger adults. Approximately 11% of adults age 18-24 years are obese compared with 25% of adults aged 55-64 years ($p<0.001$) [data not shown].[14]

Obese adults are significantly more likely to report that they are in poorer health compared with non-obese adults. About 19% of adults who are obese report that they are in fair or poor health compared with about 9% of Connecticut adults who are not obese ($p<0.001$) [data not shown].[14]

Figure 25. Age-adjusted Prevalence of Obesity among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals

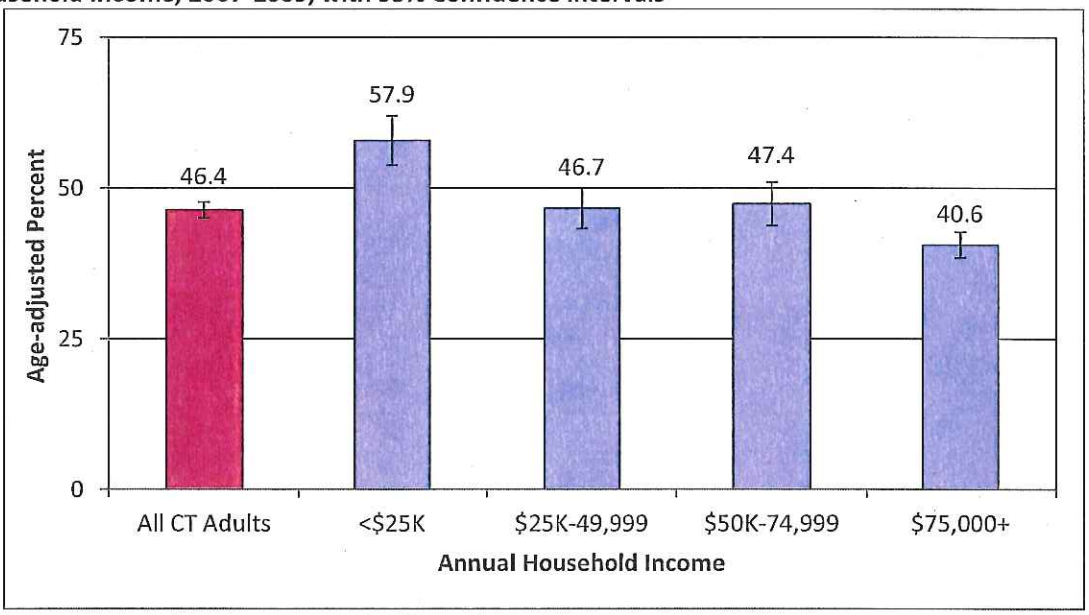
Physical Inactivity

Physical inactivity is associated with an increased risk of a number of chronic health conditions including CHD, diabetes, some cancers, HBP, obesity, and osteoporosis. Studies have shown that physical activity has protective effects on strokes.[1, 23]

The American College of Sports Medicine (ACSM), the American Heart Association (AHA), and the CDC recommend that healthy adults aged 18-65 years participate in moderate-intensity aerobic physical activity for a minimum of 30 minutes on five days per week or vigorous-intensity aerobic physical activity for a minimum of 20 minutes on three days per week.[24, 25] The guidelines are the same for adults aged 65 years and older; however, if older adults are unable to meet these guidelines because of chronic conditions, it is recommended that they participate in as much physical activity as possible.[25]

"Physical inactivity" is defined here as not meeting the recommendations of the ACSM, AHA, and CDC as described above. Approximately 47% of Connecticut adults report participating in less than the recommended amount of physical activity (2007-2009 data) compared with 49% nationwide (2009 data) (Figure 16).[14, 15] Rates of physical inactivity are higher among older adults, women, racial or ethnic minorities, and people with low incomes.[23] Physical inactivity increases with age. About 56% of adults 65 years old and older are physically inactive compared with about 48% of adults aged 45 to 64 years , and 43% of adults aged 18 to 44 years ($p<0.001$ for both comparisons) [data not shown]. Similarly, the physical inactivity rate among adults aged 45 to 64 years is significantly higher than that of adults aged 18 to 44 years ($p<0.005$) [data not shown].[14] Likewise, females are more likely to be physically inactive than males. An estimated 48.5% of adult females are physically inactive compared with 44% of adult males ($p<0.05$) [data not shown].[14] Additionally, Black and Hispanic adults are significantly more likely to report higher rates of physical inactivity than White adults ($p<0.001$ for Black and White comparison; $p<0.005$ for Hispanic and White comparison). The rates of physical inactivity among Black and Hispanic adults do not differ significantly. Approximately 44.5% of White, 59.7% of Black, and 54.2% of Hispanic adults report that they are physically inactive (data not shown).[14] Furthermore, adults with lower incomes are more likely to be physically inactive compared to adults with higher incomes. For example, about 58% of adults with annual household incomes of less than $25,000 are physically inactive compared to 41% of adults with annual household incomes of $75,000 or more ($p<0.001$) [Figure 26].[14]

Figure 26. Age-adjusted Prevalence of Physical Inactivity among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Co-Prevalence of Cardiovascular Risk Factors

The co-prevalence of risk factors places an individual at elevated risk of CHD and stroke.[26] Approximately 42% of Connecticut adults report having two or more and 19% report having three or more modifiable risk factors for CVD.[14] The co-prevalence of risk factors contributes to the complexity of disease management.

RECOGNIZING THE SIGNS AND SYMPTOMS OF HEART ATTACK AND STROKE

The *Healthy People 2010* national objectives for both heart disease and stroke include increasing the proportion of persons who are aware of the early warning signs and symptoms of heart attack and stroke and the necessity of calling 911 when persons are suffering from either of these conditions (Table 6).[8] Early recognition of heart attack and stroke and calling 911 increase the likelihood of immediate emergency transport to the hospital and timely medical care that can reduce disability and death.

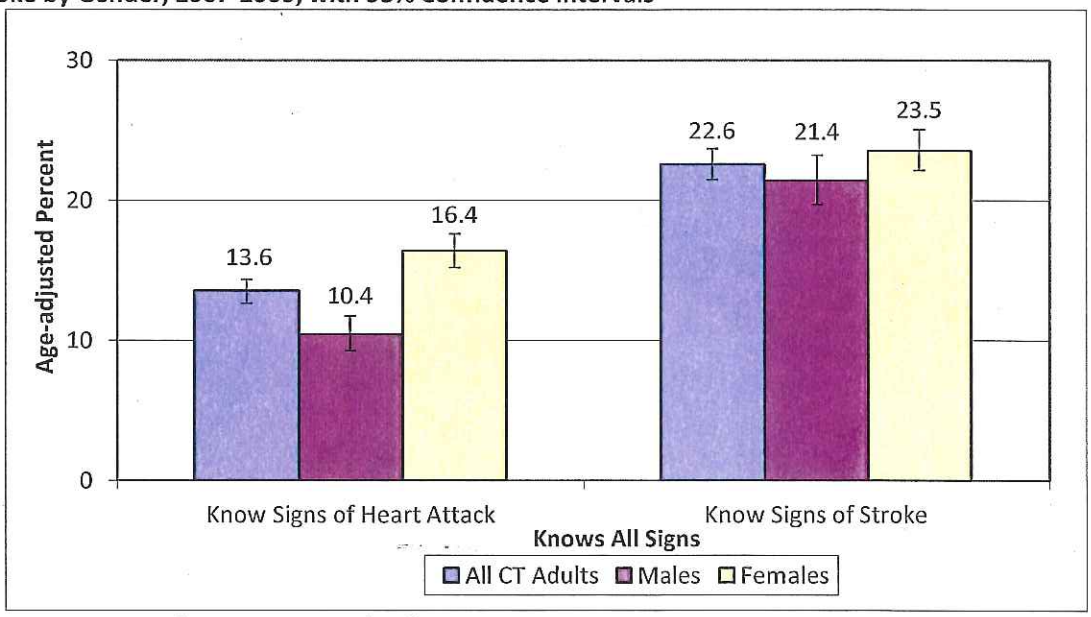
Table 6. Warning Signs for Heart Attack and Stroke

Heart Attack	Stroke
• Jaw, neck, back pain • Lightheaded, faint • Shortness of breath • Arm or shoulder discomfort • Chest pain or discomfort	• Severe headache with no known cause • Trouble seeing in one or both eyes • Confusion, trouble speaking • Trouble walking, dizziness, or loss of balance • Sudden numbness/weakness of face, arm, or leg

Source: American Heart Association, 2010.

The percentage of Connecticut adults who know all the warning signs and symptoms for heart attack and stroke tends to be very low. Only 13.6% of adults can identify all the proper heart attack signs and only 22.6% can identify all the proper stroke signs (2007-2009 data).[14] Women tend to be more knowledgeable than men about the signs and symptoms of heart attack and stroke. An estimated 16.4% of females know all heart attack signs compared with about 10.4% of males ($p<0.001$).[14] Also, approximately 23.5% of females know all signs of stroke compared with about 21.4% of males; however, this difference is not statistically significant [Figure 27].[14] Most adults, 91.4%, know that they should call 911 if they thought that someone was having a heart attack or stroke [data not shown].[14]

Figure 27. Age-adjusted Percentage of Connecticut Adults Who Know All the Signs of Heart Attack and Stroke by Gender, 2007-2009, with 95% Confidence Intervals



Source: Centers for Disease Control and Prevention, BRFSS, 2010.

ACCESS TO HEALTH CARE

Access to health care is crucial to the prevention, treatment, and management of heart disease and stroke. People without health insurance are less likely than those with health insurance to have a usual source of care, to receive preventive health care services, and to receive appropriate medical management of chronic conditions such as HBP, HBC, and diabetes.[27] About 9% of adults aged 18 and over do not have health insurance (2007-2009 data) compared with approximately 14% of adults nationwide (2009 data).[14, 15] Black and Hispanic Connecticut adults are significantly less likely to have health insurance than White Connecticut adults ($p<0.001$ for both comparisons). Approximately 6% of White, 21% of Black, and 30% of Hispanic adults do not have health insurance.[14] Comparable national figures show that about 11% of White, 21% of Black, and 31% of Hispanic adults report having no health insurance (Figure 28).[15]

Figure 28. Percentage of Adults Who Do Not Have Health Care Coverage by Race and Ethnicity, US (2009, with 5% Error Bars) and CT (2007-2009, with 95% Confidence Intervals)

TARGETING HIGH-RISK POPULATIONS

The high co-prevalence of modifiable risk factors for CVD indicates the need for public health interventions that focus on the prevention, early detection, and control of modifiable risk factors. The CDC recommends focusing efforts on increasing low dose aspirin therapy according to recognized guidelines; preventing and controlling HBC; reducing sodium intake; preventing and controlling HBC; and increasing the number of smokers counseled to quit and referred to quit lines as well as increasing the availability of no or low-cost cessations products.[28] The CDC also recommends addressing the priority areas through policies, systems, and environmental changes with the potential for broad reach and impact on the general population and high-risk populations.[28]

High-risk populations in Connecticut include Black, Hispanic, and lower-income residents. Black Connecticut residents have higher CVD and stroke mortality rates as well as higher CVD, CHD, and stroke premature mortality rates compared with White Connecticut residents. Black and Hispanic Connecticut residents have significantly higher rates of some important modifiable risk factors for CVD, such as HBC, diabetes, obesity, and physical inactivity compared with White Connecticut residents. Lower-income residents are also more likely to have higher rates of HBC, never having had cholesterol tested, diabetes, current smoking, obesity, and physical inactivity compared with higher-income residents.

Targeted, evidence-based public health interventions are warranted for all Connecticut residents with multiple risk factors. Special emphasis should be placed on interventions that address risk factor reduction among Black, Hispanic, and lower-income Connecticut residents. Evidence-based guidelines for disease prevention in the areas of diabetes, nutrition, physical activity, tobacco, and obesity are provided in the CDC's *Guide to Community Preventive Services*.[29] The 2011 Connecticut Chronic Disease planning process has focused its statewide health promotion and disease prevention efforts on policy, systems, and environmental changes at the state and local levels. Such policy, systems, and environmental changes have the potential to influence health-related behaviors in the general and high-risk populations.

APPENDICES AND REFERENCES

Appendix 1. Data Sources

Connecticut Vital Records Mortality Files

The Connecticut Vital Records Mortality Files are part of the state's vital statistics data base that contains records pertaining to deaths that occur within the state as well as deaths of Connecticut residents occurring in other states, or in Canada. Mortality statistics are compiled in accordance with the World Health Organization (WHO) regulations, which specify that deaths be classified by the current Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Deaths for the 1989-1998 period included in this report are classified by the Ninth Revision of the International Classification of Diseases [ICD-9].[30] Deaths for the 1999-2008 period are classified by the Tenth Revision of the International Classification of Diseases [ICD-10].[31]

The race-ethnicity designation is typically based on report by next of kin, a funeral director, coroner, or other official, often based on observations. As such, the race-ethnicity designation based on observation may be reported incorrectly. Another potential source of error is the fact that death rates are calculated using two different sources of data – the death certificate for the numerator and the U.S. Census Bureau population estimates for the denominator. Errors in under- or over-counting populations by race and/or ethnicity will affect the death rates reported for these groups. Mortality data are reported using racial categories that exclude persons of Hispanic origin (White, non-Hispanic and Black, non-Hispanic) and by Hispanic ethnicity (Hispanics of any race). Death Registry data follow the National Center for Health Statistics guidelines for coding race and Hispanic ethnicity.[5]

Connecticut Hospital Discharge Abstract and Billing Data Base

The Connecticut Hospital Discharge Abstract and Billing Data Base is the source of inpatient hospitalization data. It is maintained by the Connecticut Office of Health Care Access, and it contains patient-level demographic, clinical, and billing data for all non-federal acute care hospitals in the state. In addition to age, gender, and town of residence, the demographic data elements include race and ethnicity. Race and ethnicity may be based upon observation of the patient or self-reporting by the patient. Race is designated as White, non-Hispanic and Black, non-Hispanic; Hispanic ethnicity includes persons of any race.

It should be noted that counts reflect hospitalizations not persons. For example, a patient admitted to a hospital on two separate occasions in 2008 would be counted twice in these data. Another limitation of the data is the fact that it is an administrative data set. It contains diagnoses and procedures based on the International Classification of Diseases, Clinical Modification (ICD-9-CM) codes. The literature contains many reports on the reliability and validity of hospital discharge data with clinical conditions emphasizing discrepancies between ICD-9-CM codes and clinical data.[32]

Behavioral Risk Factor Surveillance System

The Behavioral Risk Factor Surveillance System (BRFSS) survey is a state-based system of health surveys that generate information about health risk behaviors, clinical preventive practices, and health care access and use. The BRFSS, sponsored by the Centers for Disease Control and Prevention, is the world's largest telephone survey, and is conducted in all 50 states. It is an on-going random sample telephone survey of non-institutionalized adults, 18 years and older. Information from the survey is used to improve the health of people nationwide and in Connecticut. Racial and ethnic classifications are based on self-report and include White, non-Hispanic, Black, non-Hispanic, and Hispanic (including persons of any race). Other national and state-specific risk factor data and information regarding BRFSS methodology can be accessed on the CDC's BRFSS Web site at: http://www.cdc.gov/brfss/.

Connecticut School Health Survey

The Connecticut School Health Survey (CSHS) is a comprehensive survey that consists of two components: Youth Tobacco Component (YTC) and the Youth Behavior Component (YBC). The CSHS is conducted by the Connecticut Department of Public Health in cooperation with the CDC, the Connecticut State Department of Education, and partners from local school health districts and local health departments. The YTC is a comprehensive survey of tobacco use, access, cessation, knowledge and attitudes, and exposure among Connecticut students in grades 6-12. The YBC collects data that is used to monitor priority health-risk behaviors and the prevalence of obesity and asthma among high school students in Connecticut. The YBC is administered to a representative sample of all regular public high school students in Connecticut. Racial and ethnic classifications are based on self-report and include White, non-Hispanic; Black, non-Hispanic; and Hispanic (including persons of any race). Further information about the CSHS can be found on the Connecticut Department of Public Health's web site: http://www.ct.gov/dph/cshs. Other national and state-specific youth risk factor data and information can be accessed on the CDC's web site: http://www.cdc.gov/HealthyYouth/YRBS/.

Appendix 2A. ICD-10 Coding for Selected Causes of Death, 1999-2008

Cause of Death	ICD-10 Code
All Causes	A00.0 – Y89.9
All Cancers	C00 – C97
Diabetes Mellitus	E10 – E14
Alzheimer's Disease	G30
Cardiovascular Disease	I00-I78
Diseases of the Heart	I00 – I09, I11, I13, I20 – I51
Coronary Heart Disease	I11, I20-I25
Congestive Heart Failure	I50.0
Essential Hypertension & Hypertensive Renal Disease	I10, I12
Cerebrovascular Disease	I60 – I69
Atherosclerosis	I71
Pneumonia and Influenza	J10 – J18
Chronic Lower Respiratory Diseases	J40 – J47
Unintentional Injuries	V01 – X59, Y85 – Y86

Appendix 3A. Glossary of Statistical Terms

Age-adjustment. "Age adjustment, using the direct method, is the application of observed age-specific rates to a standard age distribution to eliminate differences in crude rates in populations of interest that result from differences in the populations' age distributions. This adjustment is usually done when comparing two or more populations at one point in time or one population at two or more points in time. Age adjustment is particularly relevant when populations being compared have different age structures, for example, the U.S. white and Hispanic populations...."[33]

Age-adjusted BRFSS rates. Some of the Behavioral Risk Factor Surveillance System (BRFSS) rate estimates presented in this report were age-adjusted, using the direct method, in order to eliminate differences in crude rates in populations of interest that result from differences in the populations' age distributions, such as those of Hispanics and Whites. The following age distributions and age-adjustment weights, based on the 2000 projected U.S. population, were used[34]:

Age Distributions and Age-adjustment Weights, 2000 Projected U.S. Population

Age	Population in thousands	Adjustment weight
18 years and over	203,851	1.000000
18 – 24 years	26,258	0.128810
25 – 44 years	81,892	0.401725
45 – 64 years	60,991	0.299194
65 years and over	34,710	0.170271

Age-adjusted Mortality Rates (AAMR) and Age-adjusted Hospitalization Rates (AAHR) are used to compare relative mortality and hospitalization risk, respectively, across groups and over time. They are not actual measures of risk but rather an index of risk. They are weighted statistical averages of the age-specific rates, in which the weights represent the fixed population proportions by age.[35] The AAMR and AAHR were computed by the direct method. The 1940 and 2000 U.S. standard million population distributions are shown below:

Age group	1940	2000
0-4	80,057	69,136
5-9	81,151	72,533
10-14	89,209	73,032
15-19	93,665	72,169
20-24	88,002	66,477
25-29	84,280	64,529
30-34	77,787	71,044
35-39	72,501	80,762
40-44	66,744	81,851
45-49	62,696	72,118
50-54	55,116	62,716
55-59	44,559	48,454
60-64	36,129	38,793
65-69	28,519	34,264
70-74	19,519	31,773
75-79	11,423	26,999
80-84	5,878	17,842
85+	2,765	15,508
Total	1,000,000	1,000,000

Cause-of-death classification. Mortality statistics for this report were compiled in accordance with the World Health Organization (WHO) regulations, which specify that member nations classify causes of death by the current Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Deaths for the 1989-1998 period were classified by the Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death, Ninth Revision of the International Classification of Diseases (ICD-9).[30] Deaths for the 1999-2008 period were classified according to the Tenth Revision of the International Classification of Diseases (ICD-10).[31]

Healthy People 2010 is part of a national strategy addressing the prevention of major chronic illnesses, injuries, and infectious diseases. It is the product of an effort, involving expert working groups, a consortium of national organizations, all state health departments, and the Institute of Medicine of the National Academy of Sciences to set health objectives for the nation. After extensive national and regional hearings were conducted with a period of public review and comment, the health objectives were published in 1990 as *Healthy People 2000—National Health Promotion and Disease Prevention Objectives.* It established national objectives and served as the basis for the development of state and community plans. *Healthy People 2010* provides a comprehensive view of the nation's health in 2000, and establishes national goals and targets to be achieved by 2010, and monitors progress over time.[36]

Hispanic origin refers to people whose origins are from Spain, the Spanish-speaking countries of Central America, South America, and the Caribbean, or persons of Hispanic origin identifying themselves as Spanish, Spanish-American, Hispanic, Hispano, or Latino. Since 1988, the Connecticut death certificate has had a separate line item for Hispanic ethnicity. Individuals identified as "Hispanic" can be of any race, and are also counted in the race breakdown as either "white," "black," "Asian or Pacific Islander," "American Indian," or other.[5]

International Classification of Diseases 9th and 10th Revisions(ICD-9, ICD-10) have been the internationally accepted coding system for determining cause of death since the early 1900s. It is periodically revised. The Ninth Revision (ICD-9) was in use from 1975 through 1998. Beginning with 1999 deaths, the Tenth Revision (ICD-10) is being used.

Preliminary estimates of the comparability of ICD-9 to ICD-10 have been published and indicate that the discontinuity in trends from 1998 to 1999 for some leading causes of death (septicemia, influenza and pneumonia, Alzheimer's disease, nephritis, nephrotic syndrome, and nephrosis) is substantial.[37]

International Classification of Diseases, Clinical Modification (ICD-9-CM) is a coding system recommended for use in all clinical settings to describe medical procedures and diagnoses. It is required for reporting diagnoses and diseases to all U.S. Public Health Service and Department of Health and Human Services programs, including Medicare and Medicaid. The foundation of the ICD-9-CM is the *International Classification of Diseases, 9th Revision* published by the World Health Organization.[30]

Population bases for computing rates are taken from the U.S. Census Bureau's *Estimates of the population of states by age, sex, race, and Hispanic origin*. These data are estimates of the population of Connecticut by 5-year age groups (age 0 to 4, 5 to 9,...85 and over), sex (male, female), modified race (white; black; Native American including Alaska Natives; Asian and Pacific Islander) and Hispanic origin (Hispanic, non-Hispanic) for each year, July 1, 1999 through July 1, 2009.[5]

Premature mortality. See Years of Potential Life Lost.

Race refers to a population of individuals identified from a common history, nationality, or geographical place. Race is widely considered a valid scientific category, but not a valid biological or genetic category.[38, 39] Available scientific evidence indicates that racial and ethnic classifications do not capture biological distinctiveness, and that there is more genetic variation within racial groups than there is between racial groups.[40, 41] Contemporary race divisions result from historical events and circumstances and reflect current social realities. Thus, racial categories may be viewed more accurately as proxies for social and economic conditions that put individuals at higher risk for certain disease conditions.[32]

Data in this report include two racial groups in Connecticut: white, non-Hispanic and black, non-Hispanic. Individuals identified as "Hispanic" can be of any race.

Socioeconomic position refers to a person's social and economic place in a society, and is operationalized or measured by characteristics such as per capita or household income, educational attainment, or occupation. Historically, lower socioeconomic position has been strongly correlated with less favorable health outcomes such as premature mortality and higher death rates from all causes; conversely, persons of higher socioeconomic position do better on most measures of health status.[12]

Years of potential life lost (YPLL) represents the number of years of potential life lost by each death before a predetermined end point (e.g., 65 or 75 years of age). Whereas the crude and adjusted death rates are heavily influenced by the large number of deaths among the elderly, the YPLL measure provides a picture of premature mortality by weighting deaths that occur at younger ages more heavily than those occurring at older ages, thereby emphasizing different causes of death. Age-adjusted YPLLs are calculated using the methodology of Romeder and McWhinnie.[42] This method consists of a summation of the number of deaths occurring at each age (betweem 1 and 75) multiplied by the remaining years of life had the deceased lived up to age 75.

Appendix 3B. Glossary of Medical Terms

Atherosclerosis: A disease that affects the arteries, particularly those supplying the heart, the brain, the aorta, and the lower extremities. Atherosclerosis underlies the occurrence of heart attacks, many strokes, peripheral arterial disease, and ruptures of the aorta.[43]

Cardiovascular Diseases (CVD): Diseases of the circulatory system, which include acute myocardial infarction, ischemic heart disease, valvular heart disease, peripheral vascular disease, arrhythmias, high blood pressure and stroke.[44]

Coronary Heart Disease (CHD): A form of heart disease resulting from impaired circulation in one or more coronary arteries. Common clinical manifestations of CHD include chest pain (angina pectoris) or "heart attack".[44]

Cerebrovascular Disease: A disease of one or more blood vessels in the brain, which often results in the sudden development of a focal neurologic deficit, or stroke. Stroke, or a "brain attack" is the most severe clinical manifestation of cerebrovascular disease.[1, 45]

Congestive Heart Failure: The inability of the heart to maintain adequate pumping function, which can be caused by a number of factors, such as untreated hypertension, heart attacks, or infections. Heart failure increases the risk for other cardiovascular disease events and often results in physical disability. Congestive Heart Failure is commonly referred to as "heart failure".[43-45]

Diabetes (or diabetes mellitus): A metabolic disorder that results from the body's insufficient production or utilization of insulin. The most common types of diabetes includes "Type 1 diabetes," formerly known as "juvenile diabetes," and "Type 2 diabetes," formerly known as "adult-onset diabetes." Long-term effects of diabetes include cardiovascular complications.[43]

Dyslipidemia: A disorder of lipoprotein metabolism, such as an overproduction or deficiency of lipoprotein. Dyslipidemia is often manifested by elevated levels of total cholesterol, the "bad" or low-density lipoprotein (LDL) cholesterol, and the triglyceride concentrations, as well as decreased levels of the "good" or high-density lipoprotein (HDL) cholesterol concentration in the blood.[46]

Essential Hypertension: high blood pressure without a secondary cause such as renal failure. Approximately 95% of all cases of hypertension are classified as essential hypertension.[47]

Heart Failure: See Congestive Heart Failure.

Hemorrhagic Stroke: Hemorrhagic stroke occurs when a weakened blood vessels ruptures causing bleeding within the brain. The resulting accumulation of blood compresses nearby brain tissue. Hemorrhagic stroke is often associated with high blood pressure. About 13% of all strokes are hemorrhagic.[48]

High Blood Cholesterol: Cholesterol is a substance found in all cells of the body; it is carried in lipoproteins, made of fat (lipid) on the inside and proteins on the outside. Low-density lipoprotein (LDL) cholesterol is sometimes called "bad cholesterol" because it leads to a buildup of cholesterol in arteries. The chance of heart disease increases with increasing LDL levels in the blood. The buildup of cholesterol in the arteries is called plaque, which over time causes the narrowing of the arteries, or "atherosclerosis." Some plaques can burst, releasing fat and cholesterol into the bloodstream, which may cause the blood to clot and block the flow of blood. This blockage can cause angina or a heart attack. Lowering one's cholesterol level decreases the chance of having a plaque burst and a subsequent heart attack. Lowering cholesterol may also slow down, reduce, or even stop plaque from building up.[49]

High Blood Pressure: A condition in which the pressure in the arterial circulation system is greater than clinically recommended, that is a systolic pressure greater than or equal to 140 mm Hg or a diastolic pressure greater than or equal to 90 mm Hg. High blood pressure is associated with increased risk for heart disease, stroke, and chronic kidney disease.[43]

Hypertensive Heart Disease: An abnormality in the structure and function of the heart caused by long-standing high blood pressure. A common, clinical manifestation of hypertensive heart disease is heart failure.[43]

Ischemic Heart Disease: A condition in which heart muscle is damaged or works inefficiently because of an absence or deficiency of its blood supply. Ischemic heart disease is most often caused by atherosclerosis, and includes angina pectoris, acute myocardial infarction, chronic ischemic heart disease, and sudden death.[44]

Ischemic Stroke: The most common type of stroke that results from an obstruction within a blood vessel supplying blood to the brain. Atherosclerosis is the cause of the obstruction. About 87% of strokes are ischemic strokes.[50]

Obesity: Defined in terms of body mass index (BMI), and calculated as body weight in kilograms (1 kg = 2.2 lbs.) divided by height in meters (1 m = 39.37 in) squared. Adults with a BMI of greater than or equal to 30.0 kg/m2 are considered "obese," and those with a BMI of 25–29.9 kg/m2 are considered "overweight".[43]

Classification of Overweight and Obesity in Adults According to BMI.[44] Obesity is classified as BMI $\geq$ 30 kg/m^2.		
Classification	**BMI (kg/m^2)**	**Risk of Health Problems**
Underweight	< 18.5	Low (but risk of other clinical problems increased)
Normal range	18.5-24.9	Average
Overweight	25.0-29.9	Mildly increased
Obese	**> 30.0**	
Class I	30.0-34.9	Moderate
Class II	35.0-39.9	Severe
Class III	> 40.0	Very severe
Note that these values are age-independent and correspond to the same degree of fatness across different populations.		

Serum (Blood) Lipids: Cholesterol and triglycerides are types of lipids circulating in the blood. Over time, elevated cholesterol and triglycerides in the blood can become plaque in artery walls leading to atherosclerosis. Elevated cholesterol and triglyceride levels are often found in individuals with other major risk factors for heart disease (obesity, diabetes, and/or high blood pressure).[51]

Stroke: The most common clinical manifestation of cerebrovascular disease. Stroke describes an interruption of the blood supply in the brain that results in damaged brain tissue. It can be caused by clots or by bleeding in the brain from a ruptured blood vessel or a significant injury.[1, 52]

Department of Public Health
410 Capitol Avenue, MS#13HCA
P.O. Box 340308
Hartford, CT 06134

Dear Deputy Commissioner Davis:

I am writing this letter to express my support for the proposed elective angioplasty program at Greenwich Hospital as a satellite of the Yale-New Haven Heart and Vascular Center. Since the inception of the primary angioplasty program at Greenwich Hospital, I have been the Medical Director overseeing its daily operation. This program has demonstrated success and has saved lives in the community. The excellent outcomes and safety we have demonstrated with the primary angioplasty program puts us in a unique position to expand our access of high quality care to patients of this community and offer them elective angioplasty at Greenwich Hospital.

We are seeking to build on the unique structure that is already in place at Greenwich Hospital. It is cost effective and efficient to use what is already available for *emergency* angioplasty patients to also provide care to *elective* angioplasty patients. An elective angioplasty program will improve access to care locally. Patient and family satisfaction will improve as Greenwich Hospital patients will no longer have to transfer out of the region despite the availability of equipment and facilities, qualified staff and high volume operators. Currently, the transfer of patients out of the region produces an emotional, financial and occasionally physical hardship on patients and their families.

The elective angioplasty program at Greenwich Hospital would adhere to the standards set forth by the Yale-New Haven Heart and Vascular Center. We will continue the current comprehensive quality and outcome monitoring that we have created for our primary angioplasty program. Approval of an elective angioplasty program at Greenwich Hospital will improve the overall quality of the Greenwich Hospital cardiology program as it will provide the staff and operators with greater number of patients with a broader spectrum of disease to maintain competency and high quality standards.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Christopher J. Howes, MD
Medical Director of PAMI Program and Interventional
Cardiology at Greenwich Hospital
Assistant Professor of Medicine,
Yale School of Medicine

Office of Health Care Access
Department of Public Health
410 Capitol Avenue, MS#13HCA
P.O. Box 340308
Hartford, CT 06134

Dear Deputy Commissioner Davis:

I am writing this letter to express my support for the proposed elective angioplasty program at Greenwich Hospital as a satellite of the Yale-New Haven Heart and Vascular Center. As Clinical Chief of Cardiology for Yale School of Medicine and Medical Director of the Yale-New Haven Heart and Vascular Center, I have played a key role in the implementation of the primary angioplasty program at Greenwich Hospital. This program has demonstrated success and has saved lives in the community. We are seeking to build on the unique structure that is already in place at Greenwich Hospital. This program will improve continuity of care as Greenwich Hospital patients now must be transferred for elective angioplasty despite the availability of equipment and facilities, qualified staff and high volume operators.

The program will be supervised and directed by the Yale Interventional Group and all procedures will be performed by highly qualified physicians. The elective angioplasty program at Greenwich Hospital would adhere to the high standards set forth by the Yale-New Haven Heart and Vascular Center. Quality and outcomes monitoring would be provided by the Yale-New Haven Heart and Vascular Center. The facility, physicians, staff and equipment required to perform elective angioplasty services are already in place at Greenwich Hospital. It is cost effective and efficient to use what is already available for *emergency* angioplasty patients to also provide care to *elective* angioplasty patients.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Henry S. Cabin, MD
Clinical Chief of Cardiology,
Yale School of Medicine
Medical Director
Yale-New Haven Heart and Vascular Center

WESTMED
MEDICAL GROUP

Barney Newman, M.D.
Medical Director

November 17, 2011

Lisa Davis
Deputy Commissioner
Office of Health Care Access
Department of Public Health
410 Capitol Avenue, MS#13HCA
P.O. Box 340308
Hartford, CT 06134

Dear Deputy Commissioner Davis:

I am writing this letter in support of Greenwich Hospital's application to provide elective angioplasty to the communities it serves. I am the Chief Medical Officer for WESTMED Medical Group, a large multi-specialty group of over 200 physicians with locations throughout Westchester County, New York. Many of our cardiologists are on the medical staff at Greenwich Hospital. It is our experience that our patients in the Greenwich Hospital service area use the Hospital's services for their health care needs including cardiac services. If Greenwich Hospital offered elective angioplasty, we feel confident that these patients would prefer the convenient location of Greenwich Hospital along with the high quality and competent physicians and staff, up-to-date facilities and appropriate safety measures in place at the Hospital.

An elective angioplasty service at Greenwich Hospital will provide cardiac patients with local access to high quality interventional cardiology services. Patients from the Greenwich Hospital service area that need elective angioplasty are currently required to go to another hospital to receive these services since Greenwich Hospital is not approved to provide elective angioplasty services. However, the same facility, physicians, staff and equipment required to perform *elective* angioplasty services are already in place for Greenwich Hospital's approved *emergency* angioplasty program. This is a more cost effective use of resources. In addition, the ability to provide elective angioplasty will improve the continuity of care available to patients at Greenwich Hospital.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Barney D. Newman MD

Hartford, CT 06134

Dear Deputy Commissioner Davis:

I am writing this letter in support of Greenwich Hospital's application to provide elective angioplasty to the communities it serves. I am on the medical staff at Greenwich Hospital. Many of my patients use the Hospital's services for their health care needs including cardiac services. If Greenwich Hospital offered elective angioplasty, I feel confident that my patients in the Greenwich Hospital service area would prefer the convenient location of Greenwich Hospital along with the high quality and competent physicians and staff, up-to-date facilities and appropriate safety measures in place at the Hospital.

An elective angioplasty service at Greenwich Hospital will provide cardiac patients with local access to high quality interventional cardiology services. Patients from the Greenwich Hospital service area that need elective angioplasty are currently required to go to another hospital to receive these services since Greenwich Hospital is not approved to provide elective angioplasty services. However, the same facility, physicians, staff and equipment required to perform *elective* angioplasty services are already in place for Greenwich Hospital's approved *emergency* angioplasty program. This is a more cost effective use of resources. In addition, the ability to provide elective angioplasty will improve the continuity of care available to patients at Greenwich Hospital.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Glenn Gandelman, MD

PREAMBLE

The medical profession should play a central role in evaluating the evidence related to drugs, devices, and procedures for the detection, management, and prevention of disease. When properly applied, expert analysis of available data on the benefits and risks of these therapies and procedures can improve the quality of care, optimize patient outcomes, and favorably affect costs by focusing resources on the most effective strategies. An organized and directed approach to a thorough review of evidence has resulted in the production of clinical practice guidelines that assist physicians in selecting the best management strategy for an individual patient. Moreover, clinical practice guidelines can provide a foundation for other applications, such as performance measures, appropriate use criteria, and both quality improvement and clinical decision support tools.

The American College of Cardiology Foundation (ACCF) and the American Heart Association (AHA) have jointly produced guidelines in the area of cardiovascular disease since 1980. The ACCF/AHA Task Force on Practice Guidelines (Task Force), charged with developing, updating, and revising practice guidelines for cardiovascular diseases and procedures, directs and oversees this effort. Writing committees are charged with regularly reviewing and evaluating all available evidence to develop balanced, patient-centric recommendations for clinical practice.

Experts in the subject under consideration are selected by the ACCF and AHA to examine subject-specific data and write guidelines in partnership with representatives from other medical organizations and specialty groups. Writing committees are asked to perform a formal literature review; weigh the strength of evidence for or against particular tests, treatments, or procedures; and include estimates of expected outcomes where such data exist. Patient-specific modifiers, comorbidities, and issues of patient preference that may influence the choice of tests or therapies are considered. When available, information from studies on cost is considered, but data on efficacy and outcomes constitute the primary basis for the recommendations contained herein.

In analyzing the data and developing recommendations and supporting text, the writing committee uses evidence-based methodologies developed by the Task Force (1). The Class of Recommendation (COR) is an estimate of the size of the treatment effect considering risks versus benefits in addition to evidence and/or agreement that a given treatment or procedure is or is not useful/effective or in some situations may cause harm. The Level of Evidence (LOE) is an estimate of the certainty or precision of the treatment effect. The writing committee reviews and ranks evidence supporting each recommendation with the weight of evidence ranked as LOE A, B, or C according to specific definitions that are included in Table 1. Studies are identified as observational, retrospective, prospective, or randomized where appropriate. For certain conditions for which inadequate data are available, recommendations are based on expert consensus and clinical experience and are ranked as LOE C. When recommendations at LOE C are supported by historical clinical data, appropriate references (including clinical reviews) are cited if available. For issues for which sparse data are available, a survey of current practice among the clinicians on the writing committee is the basis for LOE C recommendations and no references are cited. The schema for COR and LOE is summarized in Table 1, which also provides suggested phrases for writing recommendations within each COR. A new addition to this methodology is separation of the Class III recommendations to delineate if the recommendation is determined to be of "no benefit" or is associated with "harm" to the patient. In addition, in view of the increasing number of comparative effectiveness studies, comparator verbs and suggested phrases for writing recommendations for the comparative effectiveness of one treatment or strategy versus another have been added for COR I and IIa, LOE A or B only. T1

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

TABLE 1. Applying Classification of Recommendations and Level of Evidence

ESTIMATE OF CERTAINTY (PRECISION) OF TREATMENT EFFECT	CLASS I *Benefit >>> Risk* Procedure/Treatment **SHOULD** be performed/ administered	CLASS IIa *Benefit >> Risk* *Additional studies with focused objectives needed* **IT IS REASONABLE** to perform procedure/administer treatment	CLASS IIb *Benefit ≥ Risk* *Additional studies with broad objectives needed; additional registry data would be helpful* Procedure/Treatment **MAY BE CONSIDERED**	CLASS III *No Benefit* or CLASS III *Harm* COR III: No benefit — Procedure/Test: Not Helpful; Treatment: No Proven Benefit COR III: Harm — Procedure/Test: Excess Cost w/o Benefit or Harmful; Treatment: Harmful to Patients
LEVEL A Multiple populations evaluated* Data derived from multiple randomized clinical trials or meta-analyses	■ Recommendation that procedure or treatment is useful/effective ■ Sufficient evidence from multiple randomized trials or meta-analyses	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Sufficient evidence from multiple randomized trials or meta-analyses
LEVEL B Limited populations evaluated* Data derived from a single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is useful/effective ■ Evidence from single randomized trial or nonrandomized studies	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Evidence from single randomized trial or nonrandomized studies
LEVEL C Very limited populations evaluated* Only consensus opinion of experts, case studies, or standard of care	■ Recommendation that procedure or treatment is useful/effective ■ Only expert opinion, case studies, or standard of care	■ Recommendation in favor of treatment or procedure being useful/effective ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation's usefulness/efficacy less well established ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Only expert opinion, case studies, or standard of care
Suggested phrases for writing recommendations	should is recommended is indicated is useful/effective/beneficial	is reasonable can be useful/effective/beneficial is probably recommended or indicated	may/might be considered may/might be reasonable usefulness/effectiveness is unknown/unclear/uncertain or not well established	COR III: No Benefit — is not recommended; is not indicated; should not be performed/ administered/ other; is not useful/ beneficial/ effective COR III: Harm — potentially harmful; causes harm; associated with excess morbidity/mortality; should not be performed/ administered/ other
Comparative effectiveness phrases†	treatment/strategy A is recommended/indicated in preference to treatment B treatment A should be chosen over treatment B	treatment/strategy A is probably recommended/indicated in preference to treatment B it is reasonable to choose treatment A over treatment B		

A recommendation with Level of Evidence B or C does not imply that the recommendation is weak. Many important clinical questions addressed in the guidelines do not lend themselves to clinical trials. Although randomized trials are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

*Data available from clinical trials or registries about the usefulness/efficacy in different subpopulations, such as sex, age, history of diabetes, history of prior myocardial infarction, history of heart failure, and prior aspirin use. †For comparative effectiveness recommendations (Class I and IIa; Level of Evidence A and B only), studies that support the use of comparator verbs should involve direct comparisons of the treatments or strategies being evaluated.

In view of the advances in medical therapy across the spectrum of cardiovascular diseases, the Task Force has designated the term *guideline-directed medical therapy (GDMT)* to represent optimal medical therapy as defined by ACCF/AHA guideline recommended therapies (primarily Class I). This new term, GDMT, will be used herein and throughout all future guidelines.

Because the ACCF/AHA practice guidelines address patient populations (and healthcare providers) residing in North America, drugs that are not currently available in North America are discussed in the text without a specific COR. For studies performed in large numbers of subjects outside North America, each writing committee reviews the potential influence of different practice patterns and patient populations on the treatment effect and relevance to the ACCF/AHA target population to determine whether the findings should inform a specific recommendation.

The ACCF/AHA practice guidelines are intended to assist healthcare providers in clinical decision making by describing a range of generally acceptable

ID: kandasamy.d | Black Lining: [ON] | Time: 12:16 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

approaches to the diagnosis, management, and prevention of specific diseases or conditions. The guidelines attempt to define practices that meet the needs of most patients in most circumstances. The ultimate judgment regarding care of a particular patient must be made by the healthcare provider and patient in light of all the circumstances presented by that patient. As a result, situations may arise for which deviations from these guidelines may be appropriate. Clinical decision making should involve consideration of the quality and availability of expertise in the area where care is provided. When these guidelines are used as the basis for regulatory or payer decisions, the goal should be improvement in quality of care. The Task Force recognizes that situations arise in which additional data are needed to inform patient care more effectively; these areas will be identified within each respective guideline when appropriate.

Prescribed courses of treatment in accordance with these recommendations are effective only if followed. Because lack of patient understanding and adherence may adversely affect outcomes, physicians and other healthcare providers should make every effort to engage the patient's active participation in prescribed medical regimens and lifestyles. In addition, patients should be informed of the risks, benefits, and alternatives to a particular treatment and be involved in shared decision making whenever feasible, particularly for COR IIa and IIb, where the benefit-to-risk ratio may be lower.

The Task Force makes every effort to avoid actual, potential, or perceived conflicts of interest that may arise as a result of industry relationships or personal interests among the members of the writing committee. All writing committee members and peer reviewers of the guideline are asked to disclose all such current relationships, as well as those existing 12 months previously. In December 2009, the ACCF and AHA implemented a new policy for relationships with industry and other entities (RWI) that requires the writing committee chair plus a minimum of 50% of the writing committee to have no *relevant* RWI (Appendix 1 for the ACCF/AHA definition of relevance). These statements are reviewed by the Task Force and all members during each conference call and/or meeting of the writing committee and are updated as changes occur. All guideline recommendations require a confidential vote by the writing committee and must be approved by a consensus of the voting members. Members are not permitted to write, and must recuse themselves from voting on, any recommendation or section to which their RWI apply. Members who recused themselves from voting are indicated in the list of writing committee members, and section recusals are noted in Appendix 1. Authors' and peer reviewers' RWI pertinent to this guideline are disclosed in Appendixes 1 and 2, respectively. Additionally, to ensure complete transparency, writing committee members' comprehensive disclosure information—including RWI not pertinent to this document—is available as an online supplement. Comprehensive disclosure information for the Task Force is also available online at www.cardiosource.org/ACC/ About-ACC/Leadership/Guidelines-and-Documents-Task-Forces.aspx. The work of the writing committee was supported exclusively by the ACCF, AHA, and the Society for Cardiovascular Angiography and Interventions (SCAI) without commercial support. Writing committee members volunteered their time for this activity.

In an effort to maintain relevance at the point of care for practicing physicians, the Task Force continues to oversee an ongoing process improvement initiative. As a result, in response to pilot projects, several changes to these guidelines will be apparent, including limited narrative text, a focus on summary and evidence tables (with references linked to abstracts in PubMed) and more liberal use of summary recommendation tables (with references that support LOE) to serve as a quick reference.

In April 2011, the Institute of Medicine released 2 reports: *Finding What Works in Health Care: Standards for Systematic Reviews* and *Clinical Practice Guidelines We Can Trust* (2, 3). It is noteworthy that the ACCF/AHA guidelines were cited as being compliant with many of the standards that were proposed. A thorough review of these reports and of our current methodology is under way, with further enhancements anticipated.

The recommendations in this guideline are considered current until they are superseded by a focused update or the full-text guideline is revised. Guidelines are official policy of both the ACCF and AHA.

ACCF/AHA Task Force on Practice Guidelines

1. INTRODUCTION

1.1. Methodology and Evidence Review

The recommendations listed in this document are, whenever possible, evidence based. An extensive evidence review was conducted through November 2010, as well as selected other references through August 2011. Searches were limited to studies, reviews, and other evidence conducted in human subjects and that were published in English. Key search words included but were not limited to the following: *ad hoc angioplasty, angioplasty, balloon angioplasty, clinical trial, coronary stenting, delayed angioplasty, meta-analysis,*

percutaneous transluminal coronary angioplasty, randomized controlled trial (RCT), percutaneous coronary intervention (PCI) and angina, angina reduction, antiplatelet therapy, bare-metal stents (BMS), cardiac rehabilitation, chronic stable angina, complication, coronary bifurcation lesion, coronary calcified lesion, coronary chronic total occlusion (CTO), coronary ostial lesions, coronary stent (BMS and drug-eluting stents [DES]; and BMS versus DES), diabetes, distal embolization, distal protection, elderly, ethics, late stent thrombosis, medical therapy, microembolization, mortality, multiple lesions, multi-vessel, myocardial infarction (MI), non—ST-elevation myocardial infarction (NSTEMI), no-reflow, optical coherence tomography, proton pump inhibitor (PPI), return to work, same-day angioplasty and/or stenting, slow flow, stable ischemic heart disease (SIHD), staged angioplasty, STEMI, survival, and *unstable angina (UA)*. Additional searches cross-referenced these topics with the following subtopics: *anticoagulant therapy, contrast nephropathy, PCI-related vascular complications, unprotected left main PCI, multivessel coronary artery disease (CAD), adjunctive percutaneous interventional devices, percutaneous hemodynamic support devices*, and *secondary prevention*. Additionally, the committee reviewed documents related to the subject matter previously published by the ACCF and AHA. References selected and published in this document are representative and not all-inclusive.

To provide clinicians with a comprehensive set of data, whenever deemed appropriate or when published, the absolute risk difference and number needed to treat or harm will be provided in the guideline, along with confidence intervals (CIs) and data related to the relative treatment effects such as odds ratio (OR), relative risk, hazard ratio (HR), or incidence rate ratio.

The focus of this guideline is the safe, appropriate, and efficacious performance of PCI. The risks of PCI must be balanced against the likelihood of improved survival, symptoms, or functional status. This is especially important in patients with SIHD.

1.2. Organization of the Writing Committee

The committee was composed of physicians with expertise in interventional cardiology, general cardiology, critical care cardiology, cardiothoracic surgery, clinical trials, and health services research. The committee included representatives from the ACCF, AHA, and SCAI.

1.3. Document Review and Approval

This document was reviewed by 2 official reviewers nominated by the ACCF, AHA, and SCAI, as well as 21 individual content reviewers (including members of the ACCF Interventional Scientific Council and ACCF Surgeons' Scientific Council). All information on reviewers' RWI was distributed to the writing committee and is published in this document (Appendix 2). This document was approved for publication by the governing bodies of the ACCF, AHA, and SCAI.

1.4. PCI Guidelines: History and Evolution

In 1982, a 2-page manuscript titled "Guidelines for the Performance of Percutaneous Transluminal Coronary Angioplasty" was published in *Circulation* (4). The document, which addressed the specific expertise and experience physicians should have to perform balloon angioplasty, as well as laboratory requirements and the need for surgical support, was written by an ad hoc group whose members included Andreas Grüntzig. In 1980, the ACC and the AHA established the Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures, which was charged with the development of guidelines related to the role of new therapeutic approaches and of specific noninvasive and invasive procedures in the diagnosis and management of cardiovascular disease. The first ACC/ AHA Task Force report on guidelines for coronary balloon angioplasty was published in 1988 (5). The 18-page document discussed and made recommendations about lesion classification and success rates, indications for and contraindications to balloon angioplasty, institutional review of angioplasty procedures, ad hoc angioplasty after angiography, and on-site surgical backup. Further iterations of the guidelines were published in 1993 (6), 2001 (7), and 2005 (8). In 2007 and 2009, focused updates to the guideline were published to expeditiously address new study results and recent changes in the field of interventional cardiology (9, 10). The 2009 focused update is notable in that there was direct collaboration between the writing committees for the STEMI guidelines and the PCI guidelines, resulting in a single publication of focused updates on STEMI and PCI (10).

The evolution of the PCI guideline reflects the growth of knowledge in the field and parallels the many advances and innovations in the field of interventional cardiology, including primary PCI, BMS and DES, intravascular ultrasound (IVUS) and physiologic assessments of stenosis, and newer antiplatelet and anticoagulant therapies. The 2011 iteration of the guideline continues this process, addressing ethical aspects of PCI, vascular access considerations, CAD revascularization including hybrid revascularization, revascularization before noncardiac surgery, optical coherence tomography, advanced hemodynamic support

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

devices, no-reflow therapies, and vascular closure devices. Most of this document is organized according to "patient flow," consisting of preprocedural considerations, procedural considerations, and postprocedural considerations. In a major undertaking, the STEMI, PCI, and coronary artery bypass graft (CABG) surgery guidelines were written concurrently, with additional collaboration with the SIHD guideline writing committee, allowing greater collaboration between the different writing committees on topics such as PCI in STEMI and revascularization strategies in patients with CAD (including unprotected left main PCI, multivessel disease revascularization, and hybrid procedures).

In accordance with direction from the Task Force and feedback from readers, in this iteration of the guideline, the text has been shortened, with an emphasis on summary statements rather than detailed discussion of numerous individual trials. Online supplemental evidence and summary tables have been created to document the studies and data considered for new or changed guideline recommendations.

2. CAD REVASCULARIZATION

Recommendations and text in this section are the result of extensive collaborative discussions between the PCI and CABG writing committees, as well as key members of the SIHD and UA/NSTEMI writing committees. Certain issues, such as older versus more contemporary studies, primary analyses versus subgroup analyses, and prospective versus post hoc analyses, have been carefully weighed in designating COR and LOE; they are addressed in the appropriate corresponding text. The goals of revascularization for patients with CAD are to 1) improve survival and/or 2) relieve symptoms.

Revascularization recommendations in this section are predominantly based on studies of patients with symptomatic SIHD and should be interpreted in this context. As discussed later in this section, recommendations on the type of revascularization are, in general, applicable to patients with UA/NSTEMI. In some cases (e.g., unprotected left main CAD), specific recommendations are made for patients with UA/NSTEMI or STEMI.

Historically, most studies of revascularization have been based on and reported according to angiographic criteria. Most studies have defined a "significant" stenosis as $\geq$ 70% diameter narrowing; therefore, for revascularization decisions and recommendations in this section, a "significant" stenosis has been defined as $\geq$ 70% diameter narrowing ($\geq$50% for left main CAD). Physiological criteria, such as an assessment of fractional flow reserve (FFR), has been used in deciding when revascularization is indicated. Thus, for recommendations about revascularization in this section, coronary stenoses with FFR $\leq$ 0.80 can also be considered to be "significant" (11, 12).

As noted, the revascularization recommendations have been formulated to address issues related to 1) improved survival and/or 2) improved symptoms. When one method of revascularization is preferred over the other for improved survival, this consideration, in general, takes precedence over improved symptoms. When discussing options for revascularization with the patient, he or she should understand when the procedure is being performed in an attempt to improve symptoms, survival, or both.

Although some results from the SYNTAX (Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery) study are best characterized as subgroup analyses and "hypothesis generating," SYNTAX nonetheless represents the latest and most comprehensive comparison of PCI and CABG (13, 14). Therefore, the results of SYNTAX have been considered appropriately when formulating our revascularization recommendations. Although the limitations of using the SYNTAX score for certain revascularization recommendations are recognized, the SYNTAX score is a reasonable surrogate for the extent of CAD and its complexity and serves as important information that should be considered when making revascularization decisions. Recommendations that refer to SYNTAX scores use them as surrogates for the extent and complexity of CAD.

Revascularization recommendations to improve survival and symptoms are provided in the following text and are summarized in Tables 2 and 3. References to studies comparing revascularization with medical therapy are presented when available for each anatomic subgroup. T2 T3

See Online Data Supplements 1 and 2 for additional data regarding the survival and symptomatic benefits with CABG or PCI for different anatomic subsets.

2.1. Heart Team Approach to Revascularization Decisions: Recommendations

CLASS I

1. A Heart Team approach to revascularization is recommended in patients with unprotected left main or complex CAD (14–16). *(Level of Evidence: C)*

CLASS IIa

1. Calculation of the Society of Thoracic Surgeons (STS) and SYNTAX scores is reasonable in patients with unprotected left main and complex CAD (13, 14, 17–22). *(Level of Evidence: B)*

One protocol used in RCTs (14–16, 23) often involves a multidisciplinary approach referred to as the Heart Team. Composed of an interventional cardiologist and a cardiac surgeon, the Heart Team 1) reviews the patient's medical condition and coronary anatomy, 2) determines that PCI and/or CABG are technically feasible and reasonable, and 3) discusses revascularization options with the patient before a treatment strategy is selected. Support for using a Heart Team approach comes from reports that patients with complex CAD referred specifically for PCI or CABG in concurrent trial registries have lower mortality rates than those randomly assigned to PCI or CABG in controlled trials (15, 16).

The SIHD, PCI, and CABG guideline writing committees endorse a Heart Team approach in patients with unprotected left main CAD and/or complex CAD in whom the optimal revascularization strategy is not straightforward. A collaborative assessment of revascularization options, or the decision to treat with GDMT without revascularization, involving an interventional cardiologist, a cardiac surgeon, and (often) the patient's general cardiologist, followed by discussion with the patient about treatment options, is optimal. Particularly in patients with SIHD and unprotected left main and/or complex CAD for whom a revascularization strategy is not straightforward, an approach has been endorsed that involves terminating the procedure after diagnostic coronary angiography is completed: this allows a thorough discussion and affords both the interventional cardiologist and cardiac surgeon the opportunity to discuss revascularization options with the patient. Because the STS score and the SYNTAX score have been shown to predict adverse outcomes in patients undergoing CABG and PCI, respectively, calculation of these scores is often useful in making revascularization decisions (13, 14, 17–22).

2.2. Revascularization to Improve Survival: Recommendations

Left Main CAD Revascularization

CLASS I

1. CABG to improve survival is recommended for patients with significant (≥50% diameter stenosis) left main coronary artery stenosis (24–30). *(Level of Evidence: B)*

CLASS IIa

1. PCI to improve survival is reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: 1) anatomic conditions associated with a low risk of PCI procedural complications and a high likelihood of good long-term outcome (e.g., a low SYNTAX score [≤22], ostial or trunk left main CAD); and 2) clinical characteristics that predict a significantly increased risk of adverse surgical outcomes (e.g., STS-predicted risk of operative mortality ≥5%) (13, 17, 19, 23, 31–48). *(Level of Evidence: B)*
2. PCI to improve survival is reasonable in patients with UA/NSTEMI when an unprotected left main coronary artery is the culprit lesion and the patient is not a candidate for CABG (13, 36–39, 44, 45, 47–49). *(Level of Evidence: B)*
3. PCI to improve survival is reasonable in patients with acute STEMI when an unprotected left main coronary artery is the culprit lesion, distal coronary flow is less than TIMI (Thrombolysis In Myocardial Infarction) grade 3, and PCI can be performed more rapidly and safely than CABG (33, 50, 51). *(Level of Evidence: C)*

CLASS IIb

1. PCI to improve survival may be reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: 1) anatomic conditions associated with a low to intermediate risk of PCI procedural complications and an intermediate to high likelihood of good long-term outcome (e.g., low-intermediate SYNTAX score of <33, bifurcation left main CAD); and 2) clinical characteristics that predict an increased risk of adverse surgical outcomes (e.g., moderate-severe chronic obstructive pulmonary disease, disability from previous stroke, or previous cardiac surgery; STS-predicted risk of operative mortality >2%) (13, 17, 19, 23, 31–48, 52). *(Level of Evidence: B)*

CLASS III: HARM

1. PCI to improve survival should not be performed in stable patients with significant (≥50% diameter stenosis) unprotected left main CAD who have unfavorable anatomy for PCI and who are good candidates for CABG (13, 17, 19, 24–32). *(Level of Evidence: B)*

Non-Left Main CAD Revascularization

CLASS I

1. CABG to improve survival is beneficial in patients with significant (≥70% diameter) stenoses in 3 major coronary arteries (with or without involvement of the proximal left anterior descending [LAD] artery) or in the proximal LAD plus 1 other major coronary artery (26, 30, 53–56). *(Level of Evidence: B)*

TABLE 3. Revascularization to Improve Symptoms With Significant Anatomic (≥50% Left Main or ≥70% Non-Left Main CAD) or Physiological (FFR≤0.80) Coronary Artery Stenoses

Clinical Setting	COR	LOE	References
≥1 significant stenoses amenable to revascularization and unacceptable angina despite GDMT	I–CABG I–PCI	A	(82,99–108)
≥1 significant stenoses and unacceptable angina in whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences	IIa–CABG IIa–PCI	C	N/A
Previous CABG with ≥1 significant stenoses associated with ischemia and unacceptable angina despite GDMT	IIa–PCI	C	(86,89,92)
	IIb–CABG	C	(93)
Complex 3-vessel CAD (e.g., SYNTAX score >22) with or without involvement of the proximal LAD artery and a good candidate for CABG	IIa–CABG preferred over PCI	B	(32,46,56,71,72)
Viable ischemic myocardium that is perfused by coronary arteries that are not amenable to grafting	IIb–TMR as an adjunct to CABG	B	(109–113)
No anatomic or physiologic criteria for revascularization	III: Harm–CABG III: Harm–PCI	C	N/A

CABG indicates coronary artery bypass graft; CAD, coronary artery disease; COR, class of recommendation; FFR, fractional flow reserve; GDMT, guideline-directed medical therapy; LOE, level of evidence; N/A, not applicable; PCI, percutaneous coronary intervention; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery; and TMR, transmyocardial laser revascularization.

2. CABG or PCI to improve survival is beneficial in survivors of sudden cardiac death with presumed ischemia-mediated ventricular tachycardia caused by significant (≥70% diameter) stenosis in a major coronary artery. *(CABG Level of Evidence: B* [57–59]; *PCI Level of Evidence: C* [57])

CLASS IIa

1. CABG to improve survival is reasonable in patients with significant (≥70% diameter) stenoses in 2 major coronary arteries with severe or extensive myocardial ischemia (e.g., high-risk criteria on stress testing, abnormal intracoronary hemodynamic evaluation, or >20% perfusion defect by myocardial perfusion stress imaging) or target vessels supplying a large area of viable myocardium (60–63). *(Level of Evidence: B)*
2. CABG to improve survival is reasonable in patients with mild-moderate left ventricular (LV) systolic dysfunction (ejection fraction [EF] 35% to 50%) and significant (≥70% diameter stenosis) multi-vessel CAD or proximal LAD coronary artery stenosis, when viable myocardium is present in the region of intended revascularization (30, 64–68). *(Level of Evidence: B)*
3. CABG with a left internal mammary artery (LIMA) graft to improve survival is reasonable in patients with significant (≥70% diameter) stenosis in the proximal LAD artery and evidence of extensive ischemia (30, 56, 69, 70). *(Level of Evidence: B)*
4. It is reasonable to choose CABG over PCI to improve survival in patients with complex 3-vessel CAD (e.g., SYNTAX score >22), with or without involvement of the proximal LAD artery who are good candidates for CABG (32, 46, 56, 71, 72). *(Level of Evidence: B)*
5. CABG is probably recommended in preference to PCI to improve survival in patients with multivessel CAD and diabetes mellitus, particularly if a LIMA graft can be anastomosed to the LAD artery (62, 74–81). *(Level of Evidence: B)*

CLASS IIb

1. The usefulness of CABG to improve survival is uncertain in patients with significant (≥70%) diameter stenoses in 2 major coronary arteries not involving the proximal LAD artery and without extensive ischemia (56). *(Level of Evidence: C)*
2. The usefulness of PCI to improve survival is uncertain in patients with 2- or 3-vessel CAD (with or without involvement of the proximal LAD artery) or 1-vessel proximal LAD disease (26, 53, 56, 82). *(Level of Evidence: B)*
3. CABG might be considered with the primary or sole intent of improving survival in patients with SIHD with severe LV systolic dysfunction (EF <35%) whether or not viable myocardium is present (30, 64–68, 83, 84). *(Level of Evidence: B)*
4. The usefulness of CABG or PCI to improve survival is uncertain in patients with previous CABG and extensive anterior wall ischemia on noninvasive testing (85–93). *(Level of Evidence: B)*

CLASS III: HARM

1. CABG or PCI should not be performed with the primary or sole intent to improve survival in patients with SIHD with 1 or more coronary stenoses that

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

are not anatomically or functionally significant (e.g., <70% diameter non-left main coronary artery stenosis, FFR >0.80, no or only mild ischemia on noninvasive testing), involve only the left circumflex or right coronary artery, or subtend only a small area of viable myocardium (30, 53, 60, 61, 94–98). *(Level of Evidence: B)*

2.3. Revascularization to Improve Symptoms: Recommendations

CLASS I

1. CABG or PCI to improve symptoms is beneficial in patients with 1 or more significant (≥70% diameter) coronary artery stenoses amenable to revascularization and unacceptable angina despite GDMT (82, 99–108). *(Level of Evidence: A)*

CLASS IIa

1. CABG or PCI to improve symptoms is reasonable in patients with 1 or more significant (≥70% diameter) coronary artery stenoses and unacceptable angina for whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences. *(Level of Evidence: C)*
2. PCI to improve symptoms is reasonable in patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses associated with ischemia, and unacceptable angina despite GDMT (86, 89, 92). *(Level of Evidence: C)*
3. It is reasonable to choose CABG over PCI to improve symptoms in patients with complex 3-vessel CAD (e.g., SYNTAX score >22), with or without involvement of the proximal LAD artery who are good candidates for CABG (32, 46, 56, 72, 73). *(Level of Evidence: B)*

CLASS IIb

1. CABG to improve symptoms might be reasonable for patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses not amenable to PCI, and unacceptable angina despite GDMT (93). *(Level of Evidence: C)*
2. Transmyocardial laser revascularization (TMR) performed as an adjunct to CABG to improve symptoms may be reasonable in patients with viable ischemic myocardium that is perfused by arteries that are not amenable to grafting (109–113). *(Level of Evidence: B)*

CLASS III: HARM

1. CABG or PCI to improve symptoms should not be performed in patients who do not meet anatomic (≥50% diameter left main or ≥70% non-left main stenosis diameter) or physiological (e.g., abnormal FFR) criteria for revascularization. *(Level of Evidence: C)*

2.4. CABG Versus Contemporaneous Medical Therapy

In the 1970s and 1980s, 3 RCTs established the survival benefit of CABG compared with contemporaneous (although minimal by current standards) medical therapy without revascularization in certain subjects with stable angina: the Veterans Affairs Cooperative Study (114), European Coronary Surgery Study (55), and CASS (Coronary Artery Surgery Study) (115). Subsequently, a 1994 meta-analysis of 7 studies that randomized a total of 2,649 patients to medical therapy or CABG (30) showed that CABG offered a survival advantage over medical therapy for patients with left main or 3-vessel CAD. The studies also established that CABG is more effective than medical therapy for relieving anginal symptoms. These studies have been replicated only once during the past decade. In MASS II (Medicine, Angioplasty, or Surgery Study II), patients with multivessel CAD who were treated with CABG were less likely than those treated with medical therapy to have a subsequent MI, need additional revascularization, or experience cardiac death in the 10 years after randomization (104).

Surgical techniques and medical therapy have improved substantially during the intervening years. As a result, if CABG were to be compared with GDMT in RCTs today, the relative benefits for survival and angina relief observed several decades ago might no longer be observed. Conversely, the concurrent administration of GDMT may substantially improve long-term outcomes in patients treated with CABG in comparison with those receiving medical therapy alone. In the BARI 2D (Bypass Angioplasty Revascularization Investigation 2 Diabetes) trial of patients with diabetes mellitus, no significant difference in risk of mortality in the cohort of patients randomized to GDMT plus CABG or GDMT alone was observed, although the study was not powered for this endpoint, excluded patients with significant left main CAD, and included only a small percentage of patients with proximal LAD artery disease or LV ejection fraction (LVEF) <0.50 (116). The PCI and CABG guideline writing committees endorse the performance of the ISCHEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches) trial, which will provide contemporary data on the optimal management strategy (medical therapy or revascularization with CABG or

PCI) of patients with SIHD, including multivessel CAD, and moderate to severe ischemia.

2.5. PCI Versus Medical Therapy

Although contemporary interventional treatments have lowered the risk of restenosis compared with earlier techniques, meta-analyses have failed to show that the introduction of BMS confers a survival advantage over balloon angioplasty (117–119) or that the use of DES confers a survival advantage over BMS (119, 120).

No study to date has demonstrated that PCI in patients with SIHD improves survival rates (26, 53, 56, 82, 116, 119, 121–124). Neither COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) (82) nor BARI 2D (116), which treated all patients with contemporary optimal medical therapy, demonstrated any survival advantage with PCI, although these trials were not specifically powered for this endpoint. Although 1 large analysis evaluating 17 RCTs of PCI versus medical therapy (including 5 trials of subjects with acute coronary syndromes [ACS]) found a 20% reduction in death with PCI compared with medical therapy (123), 2 other large analyses did not (119, 122). An evaluation of 13 studies reporting the data from 5,442 patients with nonacute CAD showed no advantage of PCI over medical therapy for the individual endpoints of all-cause death, cardiac death or MI, or nonfatal MI (124). Evaluation of 61 trials of PCI conducted over several decades shows that despite improvements in PCI technology and pharmacotherapy, PCI has not been demonstrated to reduce the risk of death or MI in patients without recent ACS (119).

The findings from individual studies and systematic reviews of PCI versus medical therapy can be summarized as follows:

- PCI reduces the incidence of angina (82, 99, 104, 107, 108, 125).
- PCI has not been demonstrated to improve survival in stable patients (119, 121, 122).
- PCI may increase the short-term risk of MI (82, 121, 125, 126).
- PCI does not lower the long-term risk of MI (82, 116, 119, 121, 122, 126).

2.6. CABG Versus PCI

The results of 26 RCTs comparing CABG and PCI have been published: Of these, 9 compared CABG with balloon angioplasty (75, 105, 128–142), 14 compared CABG with BMS implantation (88, 143–160), and 3 compared CABG with DES implantation (14, 161, 162).

2.6.1. CABG Versus Balloon Angioplasty or BMS. A systematic review of the 22 RCTs comparing CABG with balloon angioplasty or BMS implantation concluded the following (163):

1. Survival was similar for CABG and PCI (with balloon angioplasty or BMS) at 1 year and 5 years. Survival was similar for CABG and PCI in subjects with 1-vessel CAD (including those with disease of the proximal portion of the LAD artery) or multivessel CAD.
2. Incidence of MI was similar at 5 years after randomization.
3. Procedural stroke occurred more commonly with CABG than with PCI (1.2% versus 0.6%).
4. Relief of angina was accomplished more effectively with CABG than with PCI 1 year after randomization and 5 years after randomization.
5. During the first year after randomization, repeat coronary revascularization was performed less often after CABG than after PCI (3.8% versus 26.5%). This was also demonstrated after 5 years of follow-up (9.8% versus 46.1%). This difference was more pronounced with balloon angioplasty than with BMS.

A collaborative analysis of data from 10 RCTs comparing CABG with balloon angioplasty (6 trials) or with BMS implantation (4 trials) (164) permitted subgroup analyses of the data from the 7,812 patients. No difference was noted with regard to mortality rate 5.9 years after randomization or the composite endpoint of death or MI. Repeat revascularization and angina were noted more frequently in those treated with balloon angioplasty or BMS implantation (164). The major new observation of this analysis was that CABG was associated with better outcomes in patients with diabetes mellitus and in those >65 years old. Of interest, the relative outcomes of CABG and PCI were not influenced by other patient characteristics, including the number of diseased coronary arteries.

The aforementioned meta-analysis and systematic review (163, 164) comparing CABG and balloon angioplasty or BMS implantation were limited in several ways:

1. Many trials did not report outcomes for other important patient subsets. For example, the available data are insufficient to determine if race, obesity, renal dysfunction, peripheral arterial disease, or previous coronary revascularization affected the comparative outcomes of CABG and PCI.
2. Most of the patients enrolled in these trials were male, and most had 1- or 2-vessel CAD and normal LV systolic function (EF >50%)—subjects known

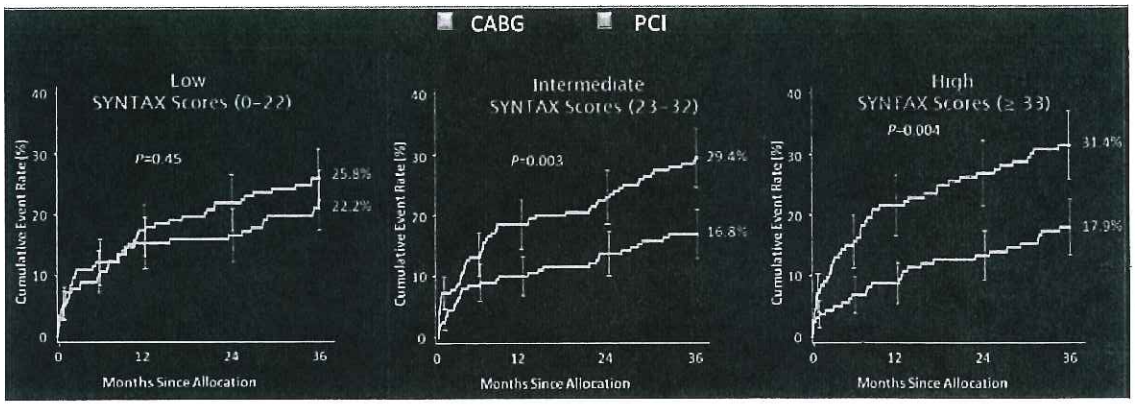

Fig. 1. Cumulative Incidence of MACE in Patients With 3-Vessel CAD Based on SYNTAX Score at 3-Year Follow-Up in the SYNTAX Trial Treated With Either CABG or PCI.

CABG indicates coronary artery bypass graft; CAD, coronary artery disease; MACE, major adverse cardiovascular event; PCI, percutaneous coronary intervention; and SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery. Adapted with permission from Kappetein (46).

to be unlikely to derive a survival benefit and less likely to experience complications after CABG (30).

3. The patients enrolled in these trials represented only a small fraction (generally <5% to 10%) of those who were screened. For example, most screened patients with 1-vessel CAD and many with 3-vessel CAD were not considered for randomization.

See Online Data Supplements 3 and 4 for additional data comparing CABG with PCI.

2.6.2. CABG Versus DES. Although the results of 9 observational studies comparing CABG and DES implantation have been published (32, 165–172), most of them had short (12 to 24 months) follow-up periods. In a meta-analysis of 24,268 patients with multivessel CAD treated with CABG or DES (173), the incidences of death and MI were similar for the 2 procedures, but the frequency with which repeat revascularization was performed was roughly 4 times higher after DES implantation. Only 1 large RCT comparing CABG and DES implantation has been published. The SYNTAX trial randomly assigned 1,800 patients (of a total of 4,337 who were screened) to receive DES or CABG (14, 46). Major adverse cardiac events (MACE), a composite of death, stroke, MI, or repeat revascularization during the 3 years after randomization, occurred in 20.2% of CABG patients and 28.0% of those undergoing DES implantation ($p<0.001$). The rates of death and stroke were similar; however, MI (3.6% for CABG, 7.1% for DES) and repeat revascularization (10.7% for CABG, 19.7% for DES) were more likely to occur with DES implantation (46).

In SYNTAX, the extent of CAD was assessed using the SYNTAX score, which is based on the location, severity, and extent of coronary stenoses, with a low score indicating less complicated anatomic CAD. In post hoc analyses, a low score was defined as ≤22; intermediate, 23 to 32; and high, ≥33. The occurrence of MACE correlated with the SYNTAX score for DES patients but not for those undergoing CABG. At 12-month follow-up, the primary endpoint was similar for CABG and DES in those with a low SYNTAX score. In contrast, MACE occurred more often after DES implantation than after CABG in those with an intermediate or high SYNTAX score (14). At 3 years of follow-up, the mortality rate was greater in subjects with 3-vessel CAD treated with PCI than in those treated with CABG (6.2% versus 2.9%). The differences in MACE between those treated with PCI or CABG increased with an increasing SYNTAX score (Figure 1) (46). F1

Although the utility of using a SYNTAX score in everyday clinical practice remains uncertain, it seems reasonable to conclude from SYNTAX and other data that outcomes of patients undergoing PCI or CABG in those with relatively uncomplicated and lesser degrees of CAD are comparable, whereas in those with complex and diffuse CAD, CABG appears to be preferable (46).

See Online Data Supplements 5 and 6 for additional data comparing CABG with DES.

2.7. Left Main CAD

2.7.1. CABG or PCI Versus Medical Therapy for Left Main CAD. CABG confers a survival benefit over medical therapy in patients with left main CAD. Subgroup analyses from RCTs performed 3 decades ago included 91 patients with left main CAD in the

Veterans Administration Cooperative Study (28). A meta-analysis of these trials demonstrated a 66% reduction in relative risk in mortality with CABG, with the benefit extending to 10 years (30). The CASS Registry (24) contained data from 1,484 patients with ≥50% diameter stenosis left main CAD initially treated surgically or nonsurgically. Median survival duration was 13.3 years in the surgical group; and 6.6 years in the medical group. The survival benefit of CABG over medical therapy appeared to extend to 53 asymptomatic patients with left main CAD in the CASS Registry (29). Other therapies that subsequently have been shown to be associated with improved long-term outcome, such as the use of aspirin, statins, and internal mammary artery grafting, were not widely used in that era.

RCTs and subgroup analyses that compare PCI with medical therapy in patients with "unprotected" left main CAD do not exist.

2.7.2. Studies Comparing PCI Versus CABG for Left Main CAD. Of all subjects undergoing coronary angiography, approximately 4% are found to have left main CAD (175), >80% of whom have significant (≥70% diameter) stenoses in other epicardial coronary arteries.

Published cohort studies have found that major clinical outcomes are similar with PCI or CABG 1 year after revascularization and that mortality rates are similar at 1, 2, and 5 years of follow-up; however, the risk of needing target-vessel revascularization is significantly higher with stenting than with CABG.

In the SYNTAX trial, 45% of screened patients with unprotected left main CAD had complex disease that prevented randomization; 89% of these underwent CABG (13, 14). In addition, 705 of the 1,800 patients who were randomized had revascularization for unprotected left main CAD. The majority of patients with left main CAD and a low SYNTAX score had isolated left main CAD or left main CAD plus 1-vessel CAD; the majority of those with an intermediate score had left main CAD plus 2-vessel CAD; and most of those with a high SYNTAX score had left main CAD plus 3-vessel CAD. At 1 year, rates of all-cause death and MACE were similar for the 2 groups (13). Repeat revascularization rates were higher in the PCI group than the CABG group (11.8% versus 6.5%), but stroke occurred more often in the CABG group (2.7% versus 0.3%). At 3 years of follow-up, the incidence of death in those undergoing left main CAD revascularization with low or intermediate SYNTAX scores (≤32) was 3.7% after PCI and 9.1% after CABG (p=0.03), whereas in those with a high SYNTAX score (≥33), the incidence of death after 3 years was 13.4% after PCI and 7.6% after CABG (p=0.10) (46). Because the primary endpoint of SYNTAX was not met (i.e., noninferiority comparison of CABG and PCI), these subgroup analyses need to be considered in that context.

In the LE MANS (Study of Unprotected Left Main Stenting Versus Bypass Surgery) trial (23), 105 patients with left main CAD were randomized to receive PCI or CABG. Although a low proportion of patients treated with PCI received DES (35%) and a low proportion of patients treated with CABG received internal mammary grafts (72%), the outcomes at 30 days and 1 year were similar between the groups. In the PRECOMBAT (Premier of Randomized Comparison of Bypass Surgery versus Angioplasty Using Sirolimus-Eluting Stent in Patients with Left Main Coronary Artery Disease) trial of 600 patients with left main disease, the composite endpoint of death, MI, or stroke at 2 years occurred in 4.4% of patients treated with PCI patients and 4.7% of patients treated with CABG, but ischemia-driven target-vessel revascularization was more often required in the patients treated with PCI (9.0% versus 4.2%) (52).

The results from these 3 RCTs suggest (but do not definitively prove) that major clinical outcomes in *selected* patients with left main CAD are similar with CABG and PCI at 1- to 2-year follow-up, but repeat revascularization rates are higher after PCI than after CABG. RCTs with extended follow-up of ≥5 years are required to provide definitive conclusions about the optimal treatment of left main CAD. In a meta-analysis of 8 cohort studies and 2 RCTs (41), death, MI, and stroke occurred with similar frequency in the PCI- and CABG-treated patients at 1, 2, and 3 years of follow-up. Target-vessel revascularization was performed more often in the PCI group at 1 year (OR: 4.36), 2 years (OR: 4.20), and 3 years (OR: 3.30).

See Online Data Supplements 7 to 12 for additional data comparing PCI with CABG for left main CAD.

2.7.3. Revascularization Considerations for Left Main CAD. Although CABG has been considered the "gold standard" for unprotected left main CAD revascularization, more recently PCI has emerged as a possible alternative mode of revascularization in carefully selected patients. Lesion location is an important determinant when considering PCI for unprotected left main CAD. Stenting of the left main ostium or trunk is more straightforward than treating distal bifurcation or trifurcation stenoses, which generally requires a greater degree of operator experience and expertise (176). In addition, PCI of bifurcation disease is associated with higher restenosis rates than when disease is confined to the ostium or trunk (39, 177). Although lesion location influences technical success and long-term outcomes after PCI, location exerts a negligible influence on the success of CABG. In subgroup analyses, patients with left main CAD and a SYNTAX score ≥33 with more

complex or extensive CAD had a higher mortality rate with PCI than with CABG (46). Physicians can estimate operative risk for all CABG candidates using a standard instrument, such as the risk calculator from the STS database. The above considerations are important factors when choosing among revascularization strategies for unprotected left main CAD and have been factored into revascularization recommendations. Use of a Heart Team approach has been recommended in cases in which the choice of revascularization is not straightforward. As discussed in Section 2.9.7, the ability of the patient to tolerate and comply with dual antiplatelet therapy (DAPT) is also an important consideration in revascularization decisions.

The 2005 PCI guideline (8) recommended routine an-giographic follow-up 2 to 6 months after stenting for unprotected left main CAD. However, because angiography has limited ability to predict stent thrombosis and the results of SYNTAX suggest good intermediate-term results for PCI in subjects with left main CAD, this recommendation was removed in the 2009 STEMI/PCI focused update (10).

Experts have recommended immediate PCI for unprotected left main CAD in the setting of STEMI (51). The impetus for such a strategy is greatest when left main CAD is the site of the culprit lesion, antegrade coronary flow is diminished (e.g., TIMI flow grade 0, 1, or 2), the patient is hemodynamically unstable, and it is believed that PCI can be performed more quickly than CABG. When possible, the interventional cardiologist and cardiac surgeon should decide together on the optimal form of revascularization for these subjects, although it is recognized that these patients are usually critically ill and therefore not amenable to a prolonged deliberation or discussion of treatment options.

2.8. Proximal LAD Artery Disease

A cohort study (53) and a meta-analysis (30) from the 1990s suggested that CABG confers a survival advantage over contemporaneous medical therapy for patients with disease in the proximal segment of the LAD artery. Cohort studies and RCTs (30, 133, 146, 148, 161, 178–181) as well as collaborative- and meta-analyses (164, 182–184) showed that PCI and CABG result in similar survival rates in these patients.

See Online Data Supplement 13 for additional data regarding proximal LAD artery revascularization.

2.9. Clinical Factors That May Influence the Choice of Revascularization

2.9.1. Diabetes Mellitus. An analysis performed in 2009 of data on 7,812 patients (1,233 with diabetes) in 10 RCTs demonstrated a worse long-term survival rate in patients with diabetes mellitus after balloon angioplasty or BMS implantation than after CABG (164). The BARI 2D trial (116) randomly assigned 2,368 patients with type 2 diabetes and CAD to undergo intensive medical therapy or prompt revascularization with PCI or CABG, according to whichever was thought to be more appropriate. By study design, those with less extensive CAD more often received PCI, whereas those with more extensive CAD were more likely to be treated with CABG.

The study was not designed to compare PCI with CABG. At 5-year follow-up, no difference in rates of survival or MACE between the medical therapy group and those treated with revascularization was noted. In the PCI stratum, no significant difference in MACE between medical therapy and revascularization was demonstrated (DES in 35%; BMS in 56%); in the CABG stratum, MACE occurred less often in the revascularization group. One-year follow-up data from the SYNTAX study demonstrated a higher rate of repeat revascularization in patients with diabetes mellitus treated with PCI than with CABG, driven by a tendency for higher repeat revascularization rates in those with higher SYNTAX scores undergoing PCI (76). In summary, in subjects requiring revascularization for multivessel CAD, current evidence supports diabetes mellitus as an important factor when deciding on a revascularization strategy, particularly when complex or extensive CAD is present (Figure 2). F2

See Online Data Supplements 14 and 15 for additional data regarding diabetes mellitus.

2.9.2. Chronic Kidney Disease. Cardiovascular morbidity and mortality rates are markedly increased in patients with chronic kidney disease (CKD) when compared with age-matched controls without CKD. The mortality rate for patients on hemodialysis is >20% per year, and approximately 50% of deaths among these patients are due to a cardiovascular cause (187, 188).

To date, randomized comparisons of coronary revascularization (with CABG or PCI) and medical therapy in patients with CKD have not been reported. Some, but not all, observational studies or subgroup analyses have demonstrated an improved survival rate with revascularization compared with medical therapy in patients with CKD and multivessel CAD (189–191), despite the fact that the incidence of periprocedural complications (e.g., death, MI, stroke, infection, renal failure) is increased in patients with CKD compared with those without renal dysfunction. Some studies have shown that CABG is associated with a greater survival benefit than PCI among patients with severe renal dysfunction (190–196).

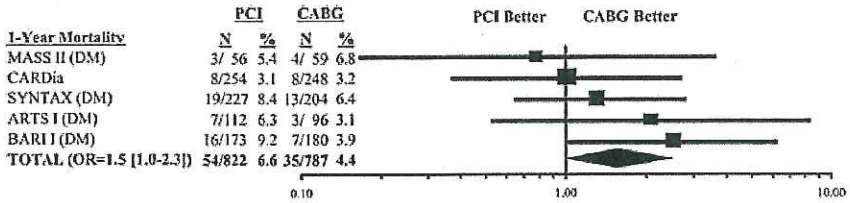

Fig. 2. 1-Year Mortality After Revascularization for Multivessel Disease and Diabetes Mellitus.

An OR of >1 suggests an advantage of CABG over PCI. ARTS I indicates Arterial Revascularization Therapy Study I (185); BARI I, Bypass Angioplasty Revascularization Investigation I (74); CABG, coronary artery bypass graft; CAD, coronary artery disease; CARDia, Coronary Artery Revascularization in Diabetes (186); CI, confidence interval; MASS II, Medicine, Angioplasty, or Surgery Study II (78); OR, odds ratio; PCI, percutaneous coronary intervention; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery; and W, weighted (76).

2.9.3. Completeness of Revascularization. Most patients undergoing CABG receive complete or nearly complete revascularization, which seems to influence long-term prognosis positively (197). In contrast, complete revascularization is accomplished less often in subjects receiving PCI (e.g., in <70% of patients), but the extent to which the absence of complete initial revascularization influences outcome is less clear. Rates of late survival and survival free of MI appears to be similar in patients with and without complete revascularization after PCI. Nevertheless, the need for subsequent CABG is usually higher in those whose initial revascularization procedure was incomplete (compared with those with complete revascularization) after PCI (198–200).

2.9.4. LV Systolic Dysfunction. Several older studies and a meta-analysis of the data from these studies reported that patients with LV systolic dysfunction (predominantly mild to moderate in severity) had better survival with CABG than with medical therapy alone (30, 64–68). For patients with more severe LV systolic dysfunction, however, the evidence that CABG results in better survival compared with medical therapy is lacking. In the STICH (Surgical Treatment for Ischemic Heart Failure) trial of subjects with LVEF <35% with or without viability testing, CABG and GDMT resulted in similar rates of survival (death from any cause, the study's primary outcome) after 5 years of follow-up. For a number of secondary outcomes at this time point, including 1) death from any cause or hospitalization for heart failure, 2) death from any cause or hospitalization for cardiovascular causes, 3) death from any cause or hospitalization for any cause, or 4) death from any cause or revascularization with PCI or CABG, CABG was superior to GDMT. Although the primary outcome (death from any cause) was similar in the 2 treatment groups after an average of 5 years of follow-up, the data suggest the possibility that outcomes would differ if the follow-up were longer in duration; as a result, the study is being continued to provide follow-up for up to 10 years (83, 84).

Only very limited data comparing PCI with medical therapy in patients with LV systolic dysfunction are available (68). In several ways, these data are suboptimal, in that many studies compared CABG with balloon angioplasty, many were retrospective, and many were based on cohort or registry data. Some of the studies demonstrated a similar survival rate in patients having CABG and PCI (71, 164, 201–203), whereas others showed that those undergoing CABG had better outcomes (32). The data that exist at present on revascularization in patients with CAD and LV systolic dysfunction are more robust for CABG than for PCI, although data from contemporary RCTs in this patient population are lacking. Therefore, the choice of revascularization in patients with CAD and LV systolic dysfunction is best based on clinical variables (e.g., coronary anatomy, presence of diabetes mellitus, presence of CKD), magnitude of LV systolic dysfunction, patient preferences, clinical judgment, and consultation between the interventional cardiologist and the cardiac surgeon.

2.9.5. Previous CABG. In patients with recurrent angina after CABG, repeat revascularization is most likely to improve survival in subjects at highest risk, such as those with obstruction of the proximal LAD artery and extensive anterior ischemia (85–93). Patients with ischemia in other locations and those with a patent LIMA to the LAD artery are unlikely to experience a survival benefit from repeat revascularization (92).

Cohort studies comparing PCI and CABG among post-CABG patients report similar rates of mid- and long-term survival after the 2 procedures (85, 88–91, 93, 204). In the patient with previous CABG who is referred for revascularization for medically refractory ischemia, factors that may support the choice of repeat CABG include vessels unsuitable for PCI, number of diseased bypass grafts, availability of the internal mammary artery for grafting chronically occluded coronary arteries, and good distal targets for bypass graft placement. Factors favoring PCI over CABG include limited areas of ischemia causing symptoms, suitable

PCI targets, a patent graft to the LAD artery, poor CABG targets, and comorbid conditions.

2.9.6. Unstable Angina/Non-ST-Elevation Myocardial Infarction. The main difference between management of the patient with SIHD and the patient with UA/NSTEMI is that the impetus for revascularization is stronger in the setting of UA/NSTEMI, because myocardial ischemia occurring as part of an ACS is potentially life threatening, and associated anginal symptoms are more likely to be reduced with a revascularization procedure than with GDMT (205–207). Thus, the indications for revascularization are strengthened by the acuity of presentation, the extent of ischemia, and the ability to achieve full revascularization. The choice of revascularization method is generally dictated by the same considerations used to decide on PCI or CABG for patients with SIHD.

2.9.7. DAPT Compliance and Stent Thrombosis: Recommendation

CLASS III: HARM

1. PCI with coronary stenting (BMS or DES) should not be performed if the patient is not likely to be able to tolerate and comply with DAPT for the appropriate duration of treatment based on the type of stent implanted (208–211). *(Level of Evidence: B)*

The risk of stent thrombosis is increased dramatically in patients who prematurely discontinue DAPT, and stent thrombosis is associated with a mortality rate of 20% to 45% (208). Because the risk of stent thrombosis with BMS is greatest in the first 14 to 30 days, this is the generally recommended minimum duration of DAPT therapy for these individuals. Consensus in clinical practice is to treat DES patients for at least 12 months with DAPT to avoid late (after 30 days) stent thrombosis (208, 212). Therefore, the ability of the patient to tolerate and comply with at least 30 days of DAPT with BMS treatment and at least 12 months of DAPT with DES treatment is an important consideration in deciding whether to use PCI to treat patients with CAD.

2.10. TMR as an Adjunct to CABG

TMR has been used on occasion in patients with severe angina refractory to GDMT in whom complete revascularization cannot be achieved with PCI and/or CABG. Although the mechanism by which TMR might be efficacious in these patients is unknown (213, 214), several RCTs of TMR as sole therapy demonstrated a reduction in anginal symptoms compared with intensive medical therapy alone (109–111, 215–217). A single randomized multicenter comparison of TMR (with a holmium: YAG laser) plus CABG and CABG alone in patients in whom some myocardial segments were perfused by arteries considered not amenable to grafting (112) showed a significant reduction in perioperative mortality rate (1.5% versus 7.6%, respectively), and the survival benefit of the TMR–CABG combination was present after 1 year of follow-up (112). At the same time, a large retrospective analysis of data from the STS National Cardiac Database as well as a study of 169 patients from the Washington Hospital Center who underwent combined TMR–CABG, showed no difference in adjusted mortality rate compared with CABG alone (113, 218). In short, a TMR–CABG combination does not appear to improve survival compared with CABG alone. In selected patients, however, such a combination may be superior to CABG alone in relieving angina.

2.11. Hybrid Coronary Revascularization: Recommendations

CLASS IIa

1. Hybrid coronary revascularization (defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries) is reasonable in patients with 1 or more of the following (219–225) *(Level of Evidence: B):*
   a. Limitations to traditional CABG, such as heavily calcified proximal aorta or poor target vessels for CABG (but amenable to PCI);
   b. Lack of suitable graft conduits;
   c. Unfavorable LAD artery for PCI (i.e., excessive vessel tortuosity or CTO).

CLASS IIb

Hybrid coronary revascularization (defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries) may be reasonable as an alternative to multivessel PCI or CABG in an attempt to improve the overall risk-benefit ratio of the procedures. *(Level of Evidence: C)*

Hybrid coronary revascularization, defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries (226), is intended to combine the advantages of CABG (i.e., durability of the LIMA graft) and PCI (227). Patients with multivessel CAD (e.g., LAD and ≥1 non-LAD stenoses) and an indication for revascularization are potentially eligible for this approach. Hybrid revascularization is ideal in patients in whom technical or anatomic limitations to CABG or PCI alone may be present and for whom minimizing the invasiveness (and therefore the risk of morbidity and mortality) of surgical intervention is preferred (221) (e.g., patients with

severe preexisting comorbidities, recent MI, a lack of suitable graft conduits, a heavily calcified ascending aorta, or a non-LAD coronary artery unsuitable for bypass but amenable to PCI, and situations in which PCI of the LAD artery is not feasible because of excessive tortuosity or CTO).

Hybrid coronary revascularization may be performed in a hybrid suite in one operative setting or as a staged procedure (i.e., PCI and CABG performed in 2 different operative suites, separated by hours to 2 days, but typically during the same hospital stay). Because most hospitals lack a hybrid operating room, staged procedures are usually performed. With the staged procedure, CABG before PCI is preferred, because this approach allows the interventional cardiologist to 1) verify the patency of the LIMA-to-LAD artery graft before attempting PCI of other vessels and 2) minimize the risk of perioperative bleeding that would occur if CABG were performed after PCI (i.e., while the patient is receiving DAPT). Because minimally invasive CABG may be associated with lower graft patency rates compared with CABG performed through a midline sternotomy, it seems prudent to angiographically image all grafts performed through a minimally invasive approach to confirm graft patency (221).

To date, no RCTs involving hybrid coronary revascularization have been published. Over the past 10 years, several small, retrospective series of hybrid revascularization using minimally invasive CABG and PCI have reported low mortality rates (0 to 2%) and event-free survival rates of83% to 92% at 6 to 12 months of follow-up. The few series that have compared the outcomes of hybrid coronary revascularization with standard CABG report similar outcomes at 30 days and 6 months (219–225).

3. PCI OUTCOMES

3.1. Definitions of PCI Success

The success of a PCI procedure is best defined by 3 interrelated components: angiographic findings, procedural events, and clinical outcomes.

3.1.1. Angiographic Success. A successful PCI produces sufficient enlargement of the lumen at the target site to improve coronary artery blood flow. A successful balloon angioplasty is defined as the reduction of a minimum stenosis diameter to <50% with a final TIMI flow grade 3 (visually assessed by angiography) without side branch loss, flow-limiting dissection, or angiographic thrombus (7). For coronary stents, a minimum stenosis diameter of <20% (as visually assessed by angiography) has previously been the clinical benchmark of an optimal angiographic result. Given improvements in technology and techniques, as well as recognition of the importance of an adequately deployed stent to decrease the risks of stent restenosis and thrombosis (12, 228, 229), the writing committee concluded that a minimum diameter stenosis of < 10% (with an optimal goal of as close to 0% as possible) should be the new benchmark for lesions treated with coronary stenting. As with balloon angioplasty, there should be final TIMI flow grade 3, without occlusion of a significant side branch, flow-limiting dissection, distal embolization, or angiographic thrombus. Problems with determining angiographic success include disparities between the visual assessment and computer-aided quantitative stenosis measurement and self-reporting of success in clinical reports or databases.

3.1.2. Procedural Success. A successful PCI should achieve angiographic success without associated in-hospital major clinical complications (e.g., death, MI, stroke, emergency CABG) (7, 8). Issues regarding the diagnosis and prognostic implications of procedure-related MI are discussed in Sections 3.3 and 5.10.

3.1.3. Clinical Success. In the short term, a clinically successful PCI requires both anatomic and procedural success along with relief of signs and/or symptoms of myocardial ischemia. Long-term clinical success requires that the short-term clinical success remain durable and that relief of signs and symptoms of myocardial ischemia persist >9 months after the procedure. Restenosis is the principal cause of lack of long-term clinical success after a short-term clinical success has been achieved. Restenosis is not a complication; it is the expected biological response to vascular injury. The frequency of clinically important restenosis may be judged by the frequency with which subsequent revascularization procedures are performed on target arteries after the index procedure.

3.2. Predictors of Clinical Outcome After PCI

Factors associated with increased PCI complication rates include advanced age, diabetes, CKD, ACS, congestive heart failure, and multivessel CAD (8, 230–232). Several models have been developed and refined over the past 2 decades to predict mortality with PCI (230, 233–236). At present, perhaps the best accepted system is from the ACC National Cardiovascular Data Registry (NCDR) CathPCI Risk Score system, which uses clinical variables and PCI setting to predict inpatient mortality (Appendix 4A)(236). In general, these models perform very well (C statistic: approximately 0.90), although predictive capability decreases in high-risk patients.

Models have also been developed to predict procedural success. Presently, the modified ACC/AHA score

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

(230) and the SCAI score (Appendix 4B)(237) are both in use, with the latter slightly outperforming the former. Discrimination as measured by the C statistic is generally good to very good (0.70 to 0.82), depending on the outcome variable and patient population.

The angiographic SYNTAX score (238) has been developed to predict long-term risk of MACE after multivessel intervention. The SYNTAX score and its potential utility in helping guide revascularization strategies are discussed in Section 2. Composite models including angiographic and clinical variables have been developed but generally require validation in larger cohorts of patients.

3.3. PCI Complications

In an analysis of the NCDR CathPCI database of patients undergoing PCI between 2004 and 2007, the overall in-hospital mortality rate was 1.27%, ranging from 0.65% in elective PCI to 4.81% in STEMI (236). Factors associated with an increased risk of PCI-related death include advanced age, comorbidities (e.g., diabetes, CKD, congestive heart failure), multivessel CAD, high-risk lesions, and the setting of PCI (e.g., STEMI, urgent or emergency procedure, cardiogenic shock) (56, 230–232, 236).

Causes of procedural and periprocedural MI include acute artery closure, embolization and no-reflow, side branch occlusion, and acute stent thrombosis. The incidence of procedure-related MI depends to a great degree on the definition of MI used, the patient population studied, and whether or not cardiac biomarkers are routinely assessed after PCI. The definition and clinical significance of PCI-related MI have been controversial. Criteria for defining a PCI-related MI have evolved over time (8, 239, 240). The 2007 universal definition of MI (240) states that after PCI, elevations of cardiac biomarkers above the 99th percentile upper reference limit indicate periprocedural myocardial necrosis. Increases of biomarkers >3 times the 99th percentile upper reference limit were designated as defining PCI-related MI (240). According to this definition, ≥15% of patients undergoing PCI would be defined as having periprocedural MI (241, 242). Issues in procedure-related MI are discussed in Section 5.10.

The need for emergency CABG has dramatically decreased with advances in PCI technology, particularly coronary stents (243, 244). Recently the NCDR reported the rate of emergency CABG at 0.4% (244). Procedure-related indications for CABG in 1 large series included coronary dissection (27%), acute artery closure (16%), perforation (8%), and failure to cross the lesion (8%) (245). The strongest predictors of the need for emergency CABG in several analyses are cardiogenic shock (OR: 11.4), acute MI or emergency PCI (OR: 3.2 to 3.8), multivessel disease (OR: 2.3 to 2.4), and type C lesion (OR: 2.6) (243, 245). In-hospital mortality for emergency CABG ranges from 7.8% to 14% (243, 245, 246).

In a contemporary analysis from the NCDR, the incidence of PCI-related stroke was 0.22% (247). In-hospital mortality in patients with PCI-related stroke is 25% to 30% (247, 248). Factors associated with an increased risk of stroke include fibrinolytic therapy administered before PCI (OR: 4.7), known cerebrovascular disease (OR: 2.20), STEMI as the indication for PCI (OR: 3.2), use of an intra-aortic balloon pump (IABP) (OR: 2.6), older age (OR: 1.17 per 5-year increase), and female sex (247–249). Initial imaging after a stroke in 1 small series revealed hemorrhagic etiology in 18%, ischemic etiology in 58%, and no clear etiology in 24% (248). One potential algorithm for the treatment of catheterization-related stroke has been recently proposed (250). This document includes no specific recommendations for the management of PCI-related stroke but refers the reader to the AHA/American Stroke Association guidelines for the management of adults with stroke (251).

Vascular complications from PCI are primarily related to vascular access. Important femoral vascular complications include access site hematoma, retroperitoneal hematoma, pseudoaneurysm, arteriovenous fistula, and arterial dissection and/or occlusion (252). The incidence of these vascular complications in various reports generally ranges from 2% to 6% and has decreased with time (249, 253–257). Factors associated with an increased risk of vascular complication include age ≥70 years, body surface area <1.6 m^2, emergency procedures, peripheral artery disease, periprocedural use of glycoprotein (GP) IIb/IIIa inhibitors, and female sex (if not corrected for body surface area) (249, 253, 254, 257, 258). Ultrasound guidance has been used for femoral artery access to potentially decrease complications (259). As discussed in Section 5.11, vascular closure devices have not been clearly demonstrated to decrease vascular complication rates. Radial site access decreases the rate of access-related bleeding and complications compared with femoral access (255, 260). Loss of the radial pulse has been reported in ≤5% of radial procedures (261). Infrequent to rare complications occurring with the radial artery approach include compartment syndrome, pseudoaneurysm (<0.01%), and sterile abscess (occurring with previous-generation hydrophilic sheaths) (262). Radial artery spasm may occur and treatment at times may be challenging. Local hematomas may occur from small-branch vessel hydrophilic wire perforation or inexperience with wristband use.

The risk of coronary perforation is approximately 0.2%, most commonly by wire perforation during PCI for CTO or by ablative or oversized devices during PCI of heavily diseased or tortuous coronary arteries (263). The risk of tamponade and management of the perforation varies with the type of perforation (264).

Periprocedural bleeding is now recognized to be associated with subsequent mortality (265, 266), and the avoidance of bleeding complications has become an important consideration in performing PCI. The risk of bleeding is associated with patient factors (e.g., advanced age, low body mass index, CKD, baseline anemia), as well as the degree of platelet and thrombin inhibition, vascular access site, and sheath size (267–269). Issues of periprocedural bleeding are discussed in Section 4.7.

The incidence of contrast-induced acute kidney injury (AKI) or "contrast nephropathy" in published reports depends on the definition of contrast nephropathy used and the frequency of risk factors for contrast-induced AKI in the patient population studied. Important risk factors for contrast-induced AKI include advanced age, CKD, congestive heart failure, diabetes, and the volume of contrast administered. Contrast-induced AKI and strategies to prevent it are discussed in Section 4.4.

4. PREPROCEDURAL CONSIDERATIONS

T4 Table 4 contains recommendations for preprocedural considerations and interventions in patients undergoing PCI.

4.1. Cardiac Catheterization Laboratory Requirements

4.1.1. Equipment. Defibrillators are considered by The Joint Commission to be life-support equipment requiring routine assessment and completion of appropriate logs. Many hospitals require periodic inspection of consoles for ancillary devices used in coronary intervention (e.g., Doppler wires, pressure-tipped sensor wires, and IVUS catheters). Point-of-care testing devices (e.g., activated clotting time and arterial blood gas machines) require routine calibration. Duration of storage of digital cine images is often mandated by law. Operating parameters for x-ray imaging equipment are adjusted at installation and periodically assessed by a qualified physicist in cooperation with the equipment manufacturer. Familiarity with radiation dose-reducing features of catheterization laboratory equipment and assistance from a qualified physicist are important for radiation dose minimization and image optimization.

4.1.2. Staffing. An interventional cardiologist must be present in the laboratory for the duration of each procedure and is responsible for procedure outcome. Nursing and technical personnel are also required to be present in the catheterization laboratory, with specific staffing dependent on state requirements and laboratory caseload and mix. Catheterization laboratory technical staff may include nurse practitioners, registered nurses, licensed vocational or practical nurses, physician assistants, nursing assistants, radiology technicians, or catheterization laboratory technicians. All catheterization laboratory staff are usually certified in basic life support, advanced cardiovascular life support, and, where appropriate, pediatric advanced life support. Catheterization laboratory personnel have a nursing degree/certification or invasive cardiovascular credentials such as registered cardiovascular invasive specialist or American Society of Radiation technologists (305).

4.1.3. 'Time-Out' Procedures. In 2003, The Joint Commission mandated a universal protocol requiring proper preoperative identification of the patient by the members of the catheterization laboratory team, marking of the operative site, and a final time-out just before the procedure (306). Although initially intended to prevent wrong-site surgery, this has been expanded to include all invasive procedures despite limited scientific evidence of its effectiveness (307). The intent of the time-out is for all members of the team to improve patient care by collectively discussing the case. The content of a time-out includes confirmation of the correct patient, correct side and site, agreement on the procedure to be performed, correct patient position, and availability of needed equipment, supplies, and implants. The timeout may be checklist driven or conversational, depending on laboratory preferences (308). The writing committee strongly endorses the practice of conducting a time-out before all PCI procedures.

4.2. Ethical Aspects

The 3 principles of medical ethics are beneficence, autonomy, and justice. Beneficence involves the physician's duty to act in the best interests of the patient and avoid maleficence, or harm *(primum non nocere)*. Autonomy describes the physician's duty to help the patient maintain control over his or her medical treatments. Justice describes the physician's duty to treat the individual patient responsibly with due consideration of other patients and stakeholders in the healthcare system. Ethical considerations specific to PCI have been previously discussed (309) and are highlighted below:

- Place the patient's best interest first and foremost when making clinical decisions (beneficence).
- Ensure that patients actively participate in decisions affecting their care (autonomy).

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

TABLE 4. Summary of Recommendations for Preprocedural Considerations and Interventions in Patients Undergoing PCI

Recommendations	COR	LOE	References
Contrast-Induced AKI			
Patients should be assessed for risk of contrast-induced AKI before PCI.	I	C	(270,271)
Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration.	I	B	(272–275)
In patients with CKD (creatinine clearance <60 mL/min), the volume of contrast media should be minimized.	I	B	(276–278)
Administration of N-acetyl-L-cysteine is not useful for the prevention of contrast-induced AKI.	III: No Benefit	A	(279–283)
Anaphylactoid reactions			
Patients with prior evidence of an anaphylactoid reaction to contrast media should receive appropriate prophylaxis before repeat contrast administration.	I	B	(252,284–286)
In patients with a prior history of allergic reactions to shellfish or seafood, anaphylactoid prophylaxis for contrast reaction is not beneficial.	III: No Benefit	C	(287–289)
Statins			
Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI.	IIa	A: Statin naive	(290–296)
		B: Chronic statin therapy	(297)
Bleeding risk			
All patients should be evaluated for risk of bleeding before PCI.	I	C	N/A
CKD			
In patients undergoing PCI, the glomerular filtration rate should be estimated and the dosage of renally cleared medications should be adjusted.	I	B	(298–300)
Aspirin			
Patients already on daily aspirin therapy should take 81 mg to 325 mg before PCI.	I	B	(301–304)
Patients not on aspirin therapy should be given nonenteric aspirin 325 mg before PCI.	I	B	(301,303,304)

AKI indicates acute kidney injury; CKD, chronic kidney disease; COR, class of recommendation; LOE, level of evidence; MI, myocardial infarction; N/A, not applicable; and PCI, percutaneous coronary intervention.

- Consider how decisions regarding one patient may also affect other patients and providers (justice).
- Plan and perform procedures and provide care with the intention of improving the patient's quality of life and/or decreasing the risk of mortality, independent of reimbursement considerations and without inappropriate bias or influence from industry, administrators, referring physicians, or other sources.
- Before performing procedures, obtain informed consent after giving an explanation regarding the details of the procedure and the risks and benefits of both the procedure and alternatives to the procedure.
- Plan and perform procedures according to standards of care and recommended guidelines, and deviate from them when appropriate or necessary in the care of individual patients.
- Seek advice, assistance, or consultation from colleagues when such consultation would benefit the patient.

4.2.1. Informed Consent. Obtaining informed consent for procedures is a legal and ethical necessity. Ideally, informed consent is obtained long enough before the procedure that the patient can fully consider informed consent issues and discuss them with family or other providers, avoiding any sense of coercion. Ad hoc PCI, or PCI immediately following diagnostic procedures, presents special problems. When informed consent for PCI is obtained before diagnostic catheterization is performed, it is impossible to predict the levels of risk and benefit from an ad hoc PCI (310, 311). If diagnostic catheterization reveals anatomy that poses a particularly high risk or for which the superiority of PCI compared with other strategies is unclear, the precatheterization informed consent discussion may be inadequate. In such cases, deferral of PCI until additional informed consent discussions and/or consultations occur may be appropriate, even though it inconveniences the patient and the healthcare system. It is the responsibility of the interventionalist to act in the patient's best interest in these circumstances.

Informed consent before emergency procedures is particularly difficult (312–314). The patient presenting with STEMI is usually in distress and often sedated, making true informed consent impossible. Rapid triage, transport, and treatment of STEMI patients create a pressured atmosphere that by necessity limits a prolonged and detailed informed consent process. Nevertheless, the interventionist must attempt to provide information about the risks and benefits of different strategies to the patient and family and balance the benefit of thorough discussion with the benefits of rapid intervention.

4.2.2. Potential Conflicts of Interest. Decisions about the performance and timing of PCI may pose additional ethical dilemmas. When considering whether to perform multivessel PCI in 1 stage versus 2 stages, safety and convenience for the patient must guide the decision, regardless of payment policies that maximize reimbursement when PCI is staged (311). A separate issue is self-referral, through which diagnostic catheterization often leads seamlessly to PCI by the same operator (315). The interventionist has an ethical obligation to the patient to consider all treatment options, consult with additional specialists (e.g., cardiac surgeons) when their input would be helpful to the patient, avoid unnecessary interventional procedures, and allow the patient to consult family members and other physicians (311).

4.3. Radiation Safety: Recommendation

CLASS I

1. Cardiac catheterization laboratories should routinely record relevant available patient procedural radiation dose data (e.g., total air kerma at the international reference point [$K_{a,r}$], air kerma air product [P_{KA}], fluoroscopy time, number of cine images), and should define thresholds with corresponding follow-up protocols for patients who receive a high procedural radiation dose. *(Level of Evidence: C)*

The issue of radiation exposure during imaging procedures has received increased attention, and the writing committee believes that radiation safety should be addressed in this guideline. Current standards for cardiac catheterization laboratories include the following:

- Specific procedures and policies are in place to minimize patient (and operator) risk.
- A radiation safety officer coordinates all radiation safety issues and works conjointly with the medical or health physicist.
- Patient radiation exposure is reduced to as low a level as reasonably can be achieved.
- Patients at increased risk for high procedural radiation exposure are identified.
- Informed consent includes radiation safety information, particularly for the high-risk patient.

A basic primer on the physics of x-ray imaging, essential to the safe practice of radiation dose management, has been published in an ACCF/AHA/Heart Rhythm Society/SCAI clinical competence statement (316). Appendix 4C summarizes strategies to minimize patient and operator radiation exposure. Adverse radiation effects are now well recognized as infrequent but potentially serious complications of prolonged interventional procedures (317). Fluoroscopic time does not include cine acquisition imaging and is therefore not an accurate measure of patient radiation dose. Total air kerma at the interventional reference point ($K_{a,r}$, in G_y) and air kerma area product (P_{KA}, in $Gycm^2$) are required to be reported on interventional x-ray systems since 2006.These are useful in the assessment of potential tissue adverse effects or long-term radiation sequelae, respectively, and it is reasonable to include them in the catheterization record at the conclusion of each procedure. Appendix 4D summarizes considerations for patient follow-up based on radiation dose during the procedure (317).

4.4. Contrast-Induced AKI: Recommendations

CLASS I

1. Patients should be assessed for risk of contrast-induced AKI before PCI (270, 271). *(Level of Evidence: C)*
2. Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration (272–275). *(Level of Evidence: B)*
3. In patients with CKD (creatinine clearance <60 mL/min), the volume of contrast media should be minimized (276–278). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. Administration of N-acetyl-L-cysteine is not useful for the prevention of contrast-induced AKI (279–283). *(Level of Evidence: A)*

See Online Data Supplements 16 to 18 for additional data regarding contrast-induced AKI.

Contrast-induced AKI or "contrast nephropathy" is one of the leading causes of hospital-acquired AKI. Major risk factors for contrast-induced AKI include advanced age, CKD, congestive heart failure, diabetes, and the volume of contrast administered. A risk-scoring system is available to predict the risk of contrast nephropathy using these risk factors and additional variables (270). Thus far, the only strategies clearly shown to reduce the risk of contrast-induced AKI are hydration and minimizing the amount of contrast media. Other than saline hydration, measures that were believed to reduce the risk of contrast-induced AKI have been found to be neutral, to have deleterious effects, or to be characterized by heterogeneous and conflicting data.

Studies of hydration to reduce the risk of contrast-induced AKI suggest that isotonic saline is preferable to half isotonic saline, intravenous (IV) hydration is preferable to oral hydration, hydration for hours before and after exposure to contrast media is preferable to a

bolus administration of saline immediately before or during contrast media exposure, and administration of isotonic saline alone is preferable to administration of isotonic saline plus mannitol or furosemide (272–275, 320). On the basis of these studies, a reasonable hydration regimen would be isotonic crystalloid (1.0 to 1.5 mL/kg per hour) for 3 to 12 hours before the procedure and continuing for 6 to 24 hours after the procedure (272–275, 284, 320, 321).

Prior studies of N-acetyl-L-cysteine and sodium bicarbonate have produced conflicting results. Some, often small, earlier studies suggested benefit, but many other more contemporary studies and meta-analyses found no clear evidence of benefit, and there are potential issues of publication bias and poor methodology issues in several analyses (279–282, 322–332). The recently completed largest randomized study on N-acetyl-L-cysteine and contrast nephropathy in patients undergoing angiographic procedures, ACT (Acetylcysteine for Contrast-Induced Nephropathy Trial), demonstrated no benefit in primary or secondary endpoints. An updated meta-analysis using only high-quality trials similarly demonstrated no benefit (283). Taken as a whole, these studies do not support any recommendation for the use of N-acetyl-L-cysteine, they do, however, provide sufficient data to conclude that N-acetyl-L-cysteine does not prevent contrast-induced AKI in patients undergoing angiographic procedures.

The correlation between the volume of contrast media and the risk of contrast-induced AKI has been documented in several studies (276, 277). Thus, minimization of contrast media volume is important to prevent contrast-induced AKI in patients undergoing angiography. The volume of contrast already administered during diagnostic catheterization is an important factor when considering possible "ad hoc" PCI.

Comparative studies of different contrast media (e.g., low-osmolar versus iso-osmolar, one agent versus another agent) have produced variable and sometimes contradictory results (334–339). Thus, current data are insufficient to justify specific recommendations about low- and isoosmolar contrast media. This issue is discussed in detail in the 2011 UA/NSTEMI focused update (340). For a further discussion of contrast media and PCI, the reader is referred to a position statement by the SCAI (284).

4.5. Anaphylactoid Reactions: Recommendations

CLASS I

1. Patients with prior evidence of an anaphylactoid reaction to contrast media should receive appropriate steroid and antihistamine prophylaxis before repeat contrast administration (252, 284–286). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. In patients with a prior history of allergic reactions to shellfish or seafood, anaphylactoid prophylaxis for contrast reaction is not beneficial (287–289). *(Level of Evidence: C)*

The incidence of anaphylactoid reactions to contrast media is $\leq$1%, and the incidence of severe reactions may be as low as 0.04% (284). Limited data suggest that in patients with a history of prior anaphylactoid reaction, the recurrence rate without prophylaxis is in the range of 16% to 44% (341). Adequate pretreatment of patients with prior anaphylactoid reactions reduces the recurrence rate to close to zero (284–286). A regimen of 50 mg of prednisone administered 13 hours, 7 hours, and 1 hour before the procedure (as well as 50 mg of diphenhydramine 1 hour before the procedure) has been shown to reduce the risk of recurrent anaphylactoid reaction (286). In practice, a regimen of 60 mg of prednisone the night before and morning of the procedure (as well as 50 mg of diphenhydramine 1 hour before the procedure) is often used (252). There are minimal data on the "pretreatment" of patients undergoing emergency PCI (342). One group has suggested IV steroids (e.g., 80 mg to 125 mg of methylprednisolone, 100 mg of hydrocortisone sodium succinate), as well as oral or IV diphenhydramine and possible IV cimetidine (284). For a more detailed discussion of issues related to contrast-induced anaphylactoid reactions, the reader is referred to several dedicated discussions on contrast agents (284, 341).

There are no data to suggest that those patients with seafood or shellfish allergies are at risk for an anaphylactoid reaction from exposure to contrast media. Iodine does not mediate seafood, shellfish, or contrast media reactions. The common misconception that seafood allergies and contrast reactions are cross-reactions to iodine probably arose from a survey published in 1975 in which 15% of patients with a history of contrast reaction reported a personal history of shellfish allergy, but nearly identical proportions of patients reported allergies to other foods, such as milk and egg, in the same survey (287). Pretreatment of patients with steroids based only on a history of seafood or shellfish allergy has a small but non-zero risk of adverse effect (e.g., hyperglycemia in a patient with diabetes) without any demonstrated benefit (288, 289).

4.6. Statin Treatment: Recommendation

CLASS IIa

1. Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI. *(Level of Evidence: A for statin-naive patients* [290–296]; *Level of Evidence: B for those on chronic statin therapy* [297])

See Online Data Supplement 19 for additional data regarding preprocedural statin treatment.

Statins have long-term benefits in patients with CAD (343, 344) and ACS (345, 346). The benefits of statins in ACS begin early, before substantial lipid lowering has occurred (345, 347), suggesting pleiotropic effects of statins. These might include anti-inflammatory effects, improvement of endothelial function, decrease of oxidative stress, or inhibition of thrombogenic responses (348). Statins were beneficial when pretreatment was started from 7 days to just before PCI (290–297).

4.7. Bleeding Risk: Recommendation

CLASS I

1. All patients should be evaluated for risk of bleeding before PCI. *(Level of Evidence: C)*

Periprocedural bleeding is now recognized as a major risk factor for subsequent mortality (265, 266). Bleeding may lead to mortality directly (because of the bleeding event) or through ischemic complications that occur when antiplatelet or anticoagulant agents are withdrawn in response to the bleeding. Bleeding may also be a marker of comorbidities associated with worse prognosis (e.g., occult cancer). The risk of bleeding is associated with a number of patient factors (e.g., advanced age, low body mass index, CKD, baseline anemia), as well as the degree of platelet and thrombin inhibition, vascular access site, and sheath size (267–269). The overall approach to PCI should be individualized to minimize both ischemic and bleeding risks.

Measures to minimize the risks of bleeding complications are discussed in several sections of this guideline. These include use of anticoagulation regimens associated with a lower risk of bleeding, weight-based dosing of heparin and other agents, use of activated clotting times to guide unfractionated heparin (UFH) dosing, avoidance of excess anticoagulation (349), dosing adjustments in patients with CKD (e.g., eptifibatide, tirofiban, bivalirudin) (350), use of radial artery access site (255), and avoidance of femoral vein cannulation when possible. Vascular closure devices have not been clearly demonstrated to decrease bleeding complications and are discussed in detail in Section 5.11.

4.8. PCI in Hospitals Without On-Site Surgical Backup: Recommendations

CLASS IIa

1. Primary PCI is reasonable in hospitals without on-site cardiac surgery, provided that appropriate planning for program development has been accomplished (351, 352). *(Level of Evidence: B)*

CLASS IIb

1. Elective PCI might be considered in hospitals without on-site cardiac surgery, provided that appropriate planning for program development has been accomplished and rigorous clinical and angiographic criteria are used for proper patient selection (352–354). *(Level of Evidence: B)*

CLASS III: HARM

1. Primary or elective PCI should not be performed in hospitals without on-site cardiac surgery capabilities without a proven plan for rapid transport to a cardiac surgery operating room in a nearby hospital or without appropriate hemodynamic support capability for transfer. *(Level of Evidence: C)*

See Online Data Supplement 20 for additional data regarding hospitals without on-site surgical backup.

Primary and elective PCI can be performed at hospitals without on-site cardiac surgical backup with a high success rate, low in-hospital mortality rate, and low rate for emergency CABG (351, 353, 354). The best outcomes for patients with STEMI are achieved at hospitals with 24/7 access to primary PCI (355). Criteria for the performance of PCI without on-site surgical backup have been proposed in an SCAI expert consensus document (352). Consideration of elective PCI without on-site cardiac surgical backup is thought to be appropriate only when performed by experienced operators with complication rates and outcomes equivalent or superior to national benchmarks. Accurate assessment of complication rates and patient outcomes via a regional or national data registry, so that outcomes can be compared with established benchmarks, is an important quality control component of any PCI program. Desires for personal or institutional financial gain, prestige, market share, or other similar motives are not appropriate considerations for initiation of PCI programs without on-site cardiac surgery. It is only appropriate to consider initiation of a PCI program without on-site cardiac surgical backup if this program will clearly fill a void in the healthcare needs of the community. Competition with another PCI program in the same geographic area, particularly an established program with surgical backup, may not be in the best interests of the community.

Tables 5 and 6 list the SCAI expert consensus document requirements for PCI programs without on-site surgical backup. Table 7 gives the requirements for primary PCI and emergency CABG at hospitals without on-site cardiac surgery, and Table 8 lists the requirements for patient and lesion selection and backup strategy for nonemergency PCI (352). Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

TABLE 5. SCAI Expert Consensus Document Personnel and Facility Requirements for PCI Programs Without On-Site Surgical Backup

Experienced nursing and technical laboratory staff with training in interventional laboratories. Personnel must be comfortable treating acutely ill patients with hemodynamic and electrical instability.
On-call schedule with operation of laboratory 24 h/d, 365 d/y.*
Experienced coronary care unit nursing staff comfortable with invasive hemodynamic monitoring, operation of temporary pacemaker, and management of IABP. Personnel capable of endotracheal intubation and ventilator management both on-site and during transfer if necessary.
Full support from hospital administration in fulfilling the necessary institutional requirements, including appropriate support services (e.g., respiratory care, blood bank).
Written agreements for emergency transfer of patients to a facility with cardiac surgery. Transport protocols should be developed and tested a minimum of 2 times per year.
Well-equipped and maintained cardiac catheterization laboratory with high-resolution digital imaging capability and IABP equipment compatible with transport vehicles. The capability for real-time transfer of images and hemodynamic data (via T-1 transmission line) as well as audio and video images to review terminals for consultation at the facility providing surgical backup support is ideal.
Appropriate inventory of interventional equipment, including guide catheters, balloons, and stents in multiple sizes; thrombectomy and distal protection devices; covered stents; temporary pacemakers; and pericardiocentesis trays. Pressure wire device and IVUS equipment are optimal but not mandatory. Rotational or other atherectomy devices should be used cautiously in these facilities because of the greater risk of perforation.
Meticulous clinical and angiographic selection criteria for PCI (Tables 6 and 7).
Performance of primary PCI as the treatment of first choice for STEMI to ensure streamlined care paths and increased case volumes. Door-to-balloon times should be tracked, and <90 min outlier cases should be carefully reviewed for process improvement opportunities. On-site rigorous data collection, outcomes analysis, benchmarking, quality improvement, and formalized periodic case review.
Participation in a national data registry where available, such as the ACC NCDR in the United States.

*Required for U.S. facilities but may not be possible for all facilities worldwide.

ACC indicates American College of Cardiology; IABP, intra-aortic balloon pump; IVUS, intravascular ultrasound; NCDR, National Cardiovascular Data Registry; PCI, percutaneous coronary intervention; SCAI, Society for Cardiovascular Angiography and Interventions; and STEMI, ST-elevation myocardial infarction.

Adapted with permission from Dehmer et al. (352).

TABLE 6. SCAI Expert Consensus Document Requirements for Off-Site Surgical Backup

Interventional cardiologists establish a working relationship with cardiac surgeons at the receiving facility.
1. Cardiac surgeon must have privileges at the referring facility to allow review of treatment options as time allows.
2. Cardiac surgeon and receiving hospital agree to provide cardiac surgical backup for urgent cases at all hours and for elective cases at mutually agreed hours.
3. Surgeon and receiving facility ensure that patients will be accepted based on medical condition, capacity of surgeon to provide services at the time of request, and availability of resources. If this cannot be ensured before the start of an elective procedure, the case should not be done at this time.
4. Interventional cardiologists must review with surgeons the immediate needs and status of any patient transferred for urgent surgery.
5. Hospital administrations from both facilities endorse transfer agreement.
6. Transferring and receiving facilities establish a rigorous protocol for rapid transfer of patients, including the proper personnel with appropriate experience.
7. A transport provider is available to begin transport within 20 min of the request and provide vehicle/helicopter with necessary life-sustaining equipment, including IABP and monitoring capability.
8. Transferring physician obtains consent for surgery from patient or appropriate surrogate.
9. Initial informed consent for PCI discloses that the procedure is being done without on-site surgical backup and acknowledges the possibility of risks related to transfer. The consent process should include the risk of urgent surgery (approximately 0.3%) and state that a written plan for transfer exists.
10. As part of the local continuous quality improvement program, a regular review of all patients transferred for emergency surgery with the outcome of surgery and identification of any improvement opportunities.

IABP indicates intra-aortic balloon pump; PCI, percutaneous coronary intervention; and SCAI, Society for Cardiovascular Angiography and Interventions.

5. PROCEDURAL CONSIDERATIONS

5.1. Vascular Access: Recommendation

CLASS IIa

1. The use of radial artery access can be useful to decrease access site complications (255, 260, 356–362). *(Level of Evidence: A)*

See Online Data Supplement 21 for additional data regarding radial access.

Femoral artery access remains the most commonly used approach in patients undergoing PCI in the United States. Choosing a femoral artery puncture site is facilitated by fluoroscopic landmark identification or ultrasound guidance. Low punctures have a high incidence of peripheral artery complications, whereas high punctures have an increased risk of retroperitoneal hemorrhage. In patients with a synthetic graft, arterial access is possible after the graft is a few months old and complication rates are not increased (254).

Radial site access is used frequently in Europe and Canada but not in the United States (260). A learning curve exists for the radial approach that will affect procedure time and radiation dose, with a trend toward lower procedural success rates for radial versus femoral access (255). However, compared with femoral access, radial access decreases the rate of access-related bleeding and complications (255, 260, 363). In a recent large RCT comparing radial and femoral access in patients with ACS undergoing PCI, there was no difference in the primary composite endpoint (death, MI, stroke, major bleeding), although there was a lower rate of vascular complications with the use of radial access (362).

TABLE 7. SCAI Expert Consensus Document Requirements for Primary PCI and Emergency Aortocoronary Bypass Surgery at Hospitals Without On-Site Cardiac Surgery

Avoid intervention in patients with

- >50% diameter stenosis of left main artery proximal to infarct-related lesion, especially if the area in jeopardy is relatively small and overall LV function is not severely impaired
- Long, calcified, or severely angulated target lesions at high risk for PCI failure with TIMI flow grade 3 present during initial diagnostic angiography
- Lesions in other than the infarct artery (unless they appeared to be flow limiting in patients with hemodynamic instability or ongoing symptoms)
- Lesions with TIMI flow grade 3 that are not amenable to stenting in patients with left main or 3-vessel disease that will require coronary bypass surgery
- Culprit lesions in more distal branches jeopardizing only a modest amount of myocardium when there is more proximal disease that could be worsened by attempted intervention

Transfer emergently for coronary bypass surgery patients with

- High-grade left main or 3-vessel coronary disease with clinical or hemodynamic instability after successful or unsuccessful PCI of an occluded vessel and preferably with IABP support
- Failed or unstable PCI result and ongoing ischemia, with IABP support during transfer

IABP indicates intra-aortic balloon pump; LV, left ventricular; PCI, percutaneous coronary intervention; SCAI, Society for Cardiovascular Angiography and Interventions; and TIMI, Thrombolysis In Myocardial Infarction.

Adapted with permission from Dehmer et al. (352).

Radial artery access is particularly appealing in patients with coagulopathy, elevated international normalized ratio due to warfarin, or morbid obesity.

5.2. PCI in Specific Clinical Situations

5.2.1. UA/NSTEMI: Recommendations

CLASS I

1. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in UA/NSTEMI patients who have refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures) (207, 364, 365). *(Level of Evidence: B)*
2. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in initially stabilized UA/ NSTEMI patients (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events (207, 365–367). *(Level of Evidence: A)*
3. The selection of PCI or CABG as the means of revascularization in the patient with ACS should generally be based on the same considerations as those without ACS (53, 156, 207, 368). *(Level of Evidence: B)*

TABLE 8. SCAI Expert Consensus Document Requirements for Patient and Lesion Selection and Backup Strategy for Nonemergency PCI by Experienced Operators at Hospitals Without On-Site Cardiac Surgery

Patient risk: expected clinical risk in case of occlusion caused by procedure

High patient risk: Patients with any of the following:

- Decompensated congestive heart failure (Killip Class 3) without evidence for active ischemia, recent CVA, advanced malignancy, known clotting disorders
- LVEF <25%
- Left main stenosis (≥50% diameter) or 3-vessel disease unprotected by prior bypass surgery (>70% stenoses in the proximal segment of all major epicardial coronary arteries)
- Single-target lesion that jeopardizes >50% of remaining viable myocardium

Lesion risk: probability that procedure will cause acute vessel occlusion

Increased lesion risk: lesions in open vessels with any of the following characteristics:

- Diffuse disease (>2 cm in length) and excessive tortuosity of proximal segments
- More than moderate calcification of a stenosis or proximal segment
- Location in an extremely angulated segment (>90%)
- Inability to protect major side branches
- Degenerated older vein grafts with friable lesions
- Substantial thrombus in the vessel or at the lesion site
- Any other feature that may, in the operator's judgment, impede successful stent deployment Aggressive measures to open CTOs are also discouraged because of an increased risk of perforation.

Strategy for surgical backup based on lesion and patient risk:

- **High-risk patients with high-risk lesions** should not undergo nonemergency PCI at a facility without on-site surgery.
- **High-risk patients with non-high-risk lesions:** Nonemergency patients with this profile may undergo PCI, but confirmation that a cardiac surgeon and operating room are immediately available is necessary.
- **Non-high-risk patients with high-risk lesions** require no additional precautions.
- **Non-high-risk patients with non-high-risk lesions** require no additional precautions. Best scenario for PCI without on-site surgery.

CTO indicates chronic total occlusion; CVA, cerebrovascular accident; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; and SCAI, Society for Cardiovascular Angiography and Interventions.

Adapted with permission from Dehmer et al. (352).

CLASS III: NO BENEFIT

1. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with extensive comorbidities (e.g., liver or pulmonary failure, cancer) in whom *(Level of Evidence: C)*
   a. The risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization,
   b. There is a low likelihood of ACS despite acute chest pain, or
   c. Consent to revascularization will not be granted regardless of the findings.

The goals of coronary angiography and revascularization in UA/NSTEMI patients are to reduce the risk of death and MI and provide symptom relief. To improve prognosis, early risk stratification is essential for selection of medical and/or invasive treatment strategies. Indications for revascularization depend on the patient's clinical risk characteristics and coronary anatomy and are in general stronger in the presence of high-risk clinical presentation (e.g., dynamic electrocardiogram [ECG] changes, elevated troponin, high Global Registry of Acute Coronary Events score), recurrent symptoms, threatened viable myocardium, CKD, and larger ischemic burden (Appendix 4E). For choice of revascularization technique, the anatomical considerations are generally those used for stable CAD, although PCI may initially be performed in the index lesion to stabilize the patient (Section 2).

Contemporary studies variably comparing strategies of very early (within hours of admission), early (within 24 hours of admission), and delayed (1 to 7 days after admission) cardiac catheterization and revascularization support a strategy of *early* angiography and revascularization to reduce the risk of recurrent ischemia and MI, particularly among those at high risk (e.g., Global Registry of Acute Coronary Events score >140) (367, 369, 370), whereas a delayed approach is reasonable in low-intermediate risk patients (based on clinical course). There is no evidence that incremental benefit is derived by angiography and PCI performed within the first few hours of hospital admission (207, 367, 371–378).

5.2.2. ST-Elevation Myocardial Infarction

5.2.2.1. CORONARY ANGIOGRAPHY STRATEGIES IN STEMI: RECOMMENDATIONS

CLASS I

1. A strategy of immediate coronary angiography with intent to perform PCI (or emergency CABG) in patients with STEMI is recommended for
   a. Patients who are candidates for primary PCI (351, 379–382). *(Level of Evidence: A)*
   b. Patients with severe heart failure or cardiogenic shock who are suitable candidates for revascularization (383, 384). *(Level of Evidence: B)*

CLASS IIa

1. A strategy of immediate coronary angiography (or transfer for immediate coronary angiography) with intent to perform PCI is reasonable for patients with STEMI, a moderate to large area of myocardium at risk, and evidence of failed fibrinolysis (385, 386). *(Level of Evidence: B)*
2. A strategy of coronary angiography (or transfer for coronary angiography) 3 to 24 hours after initiating fibrinolytic therapy with intent to perform PCI is reasonable for hemodynamically stable patients with STEMI and evidence for successful fibrinolysis when angiography and revascularization can be performed as soon as logistically feasible in this time frame (387–391). *(Level of Evidence: A)*

CLASS IIb

1. A strategy of coronary angiography performed before hospital discharge might be reasonable in stable patients with STEMI who did not undergo cardiac catheterization within 24 hours of STEMI onset. *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. A strategy of coronary angiography with intent to perform PCI is not recommended in patients with STEMI in whom the risks of revascularization are likely to outweigh the benefits or when the patient or designee does not want invasive care. *(Level of Evidence: C)*

The historical reperfusion strategies of "primary PCI," "immediate PCI," "rescue PCI," "deferred PCI," "facilitated PCI," and the "pharmacoinvasive strategy" have evolved in parallel with advances in antithrombotic therapy and STEMI prehospital and hospital systems of care. The clinical challenge in primary PCI is achieving rapid time to treatment and increasing patient access to this preferred reperfusion strategy. The clinical challenge in patients treated with fibrinolytic therapy is deciding for whom and when to perform coronary angiography.

In unstable patients (e.g., severe heart failure or cardiogenic shock, hemodynamically compromising ventricular arrhythmias) not treated initially with primary PCI, a strategy of immediate coronary angiography with intent to perform PCI is implemented unless invasive management is considered futile or unsuitable given the clinical circumstances (383, 384).

In stable patients treated with fibrinolytic therapy and clinical suspicion of reperfusion failure, a strategy of immediate coronary angiography followed by PCI improves outcome in those at high risk (385, 386). Such a strategy is also implemented in patients with evidence for infarct artery reocclusion (Table 9). The T9
clinical diagnosis of failed fibrinolysis is difficult but is best made when there is <50% ST-segment resolution 90 minutes after initiation of therapy in the lead showing the greatest degree of ST-segment elevation at presentation. Given the association between bleeding events and adverse cardiac events, a reasonable approach is to select moderate- and high-risk patients for PCI and treat low-risk patients with medical therapy. ECG and clinical findings of anterior MI or

inferior MI with right ventricular involvement or precordial ST-segment depression, as well as ongoing pain, usually predicts increased risk and the greatest potential benefit (392). Conversely, patients with symptom resolution, improving ST-segment elevation, or inferior MI localized to 3 ECG leads probably gain little benefit.

In stable patients treated with fibrinolytic therapy and clinical evidence for successful reperfusion, an early invasive strategy with cardiac catheterization performed within 24 hours decreases reinfarction and recurrent ischemic events (388, 390, 391). Because of the associated increased bleeding risk, very early (<2 to 3 hours) catheterization after administration of fibrinolytic therapy with intent to perform revascularization should be reserved for patients with evidence of failed fibrinolysis and significant myocardial jeopardy for whom immediate angiography and revascularization would be appropriate (393).

5.2.2.2. PRIMARY PCI OF THE INFARCT ARTERY: RECOMMENDATIONS

CLASS I

1. Primary PCI should be performed in patients within 12 hours of onset of STEMI (379–382). *(Level of Evidence: A)*
2. Primary PCI should be performed in patients with STEMI presenting to a hospital with PCI capability within 90 minutes of first medical contact as a systems goal (394, 395). *(Level of Evidence: B)*
3. Primary PCI should be performed in patients with STEMI presenting to a hospital without PCI capability within 120 minutes of first medical contact as a systems goal (396–398). *(Level of Evidence: B)*
4. Primary PCI should be performed in patients with STEMI who develop severe heart failure or cardiogenic shock and are suitable candidates for revascularization as soon as possible, irrespective of time delay (383, 384). *(Level of Evidence: B)*
5. Primary PCI should be performed as soon as possible in patients with STEMI and contraindications to fibrinolytic therapy with isch-emic symptoms for less than 12 hours (399, 400). *(Level of Evidence: B)*

CLASS IIa

1. Primary PCI is reasonable in patients with STEMI if there is clinical and/or electrocardiographic evidence of ongoing ischemia between 12 and 24 hours after symptom onset (401–403). *(Level of Evidence: B)*

CLASS IIb

1. Primary PCI might be considered in asymptomatic patients with STEMI and higher risk presenting between 12 and 24 hours after symptom onset. *(Level of Evidence: C)*

CLASS III: HARM

1. PCI should not be performed in a noninfarct artery at the time of primary PCI in patients with STEMI without hemodynamic compromise (404–408). *(Level of Evidence: B)*

Primary PCI is preferred to fibrinolytic therapy when time-to-treatment delays are short and the patient presents to a high-volume, well-equipped center staffed with expert interventional cardiologists and skilled support staff. Compared with fibrinolytic therapy in RCTs, primary PCI produces higher rates for infarct artery patency, TIMI flow grade 3, and lower rates for recurrent ischemia, reinfarction, emergency repeat revascularization procedures, intracranial hemorrhage, and death (379). Early, successful PCI also greatly decreases the complications of STEMI that result from longer ischemic times or unsuccessful fibrinolytic therapy, allowing earlier hospital discharge and resumption of daily activities. The greatest

*Systems goal of performing primary PCI within 90 min of first medical contact when the patient presents to a hospital with PCI capability (394, 395)(Class *I; LOE: B)* and within 120 min when the patient presents to a hospital without PCI capability (396–398) (Class *I; LOE:* B).
COR indicates class of recommendation; LOE, level of evidence; N/A, not applicable; PCI, percutaneous coronary intervention; and STEMI, ST-elevation myocardial infarction.

mortality benefit of primary PCI is in high-risk patients. PCI outcomes may not be as successful with prolonged time-to-treatment or low-volume hospitals and operators (Table 10).

Several reports have shown excellent outcomes for patients with STEMI undergoing interhospital transfer where first medical contact-to-door balloon time modestly exceeded the systematic goal of <90 minutes (396–398, 409). In these reports, the referring hospital and the receiving hospital established a transfer protocol that minimized transfer delays, and outcomes were similar to those of direct-admission patients. On the basis of these results, the PCI and STEMI guideline writing committees have modified the first medical contact-to-device time goal from 90 minutes to 120 minutes for interhospital transfer patients (397), while emphasizing that systems should continue to strive for times ≤90 minutes. Hospitals that cannot meet these criteria should use fibrinolytic therapy as their primary reperfusion strategy.

PCI of a noninfarct artery at the time of primary PCI in stable patients is associated with worse clinical outcomes unless the patient is in cardiogenic shock where PCI of a severe stenosis in a coronary artery supplying a large territory of myocardium might improve hemodynamic stability (404, 406, 408). Delayed PCI can be performed in noninfarct arteries at a later time if clinically indicated (410–412).

5.2.2.3. DELAYED OR ELECTIVE PCI IN PATIENTS WITH STEMI: RECOMMENDATIONS

CLASS IIa

1. PCI is reasonable in patients with STEMI and clinical evidence for fibrinolytic failure or infarct artery reocclusion (385, 386). *(Level of Evidence: B)*
2. PCI is reasonable in patients with STEMI and a patent infarct artery 3 to 24 hours after fibrinolytic therapy (390, 391). *(Level of Evidence: B)*
3. PCI is reasonable in patients with STEMI who demonstrate ischemia on noninvasive testing (410, 411). *(Level of Evidence: B)*

CLASS IIb

1. PCI of a hemodynamically significant stenosis in a patent infarct artery greater than 24 hours after STEMI may be considered as part of an invasive strategy (413–417). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. PCI of a totally occluded infarct artery greater than 24 hours after STEMI should not be performed in asymptomatic patients with 1- or 2-vessel disease if patients are hemodynamically and electrically stable and do not have evidence of severe ischemia (418–420). *(Level of Evidence: B)*

Studies and meta-analyses suggest potential benefit for PCI in fibrinolytic failure (385, 386). In stable

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

patients treated with fibrinolytic therapy and clinical evidence for successful reperfusion, an early invasive strategy with cardiac catheter-ization performed within 24 hours decreases reinfarction and recurrent ischemic events (388, 390, 391).

PCI for a hemodynamically significant stenosis in a patent infarct artery >24 hours after STEMI as part of a revascularization strategy improves outcome (410, 411, 413–417). PCI of an occluded infarct artery 1 to 28 days after MI in asymptomatic patients without evidence of myocardial ischemia has no incremental benefit beyond optimal medical therapy with aspirin, beta blockers, angiotensin-converting enzyme inhibitors, and statins in preserving LV function and preventing subsequent cardiovascular events (418–420). It is important to note that elective PCI of an occluded infarct artery has not been studied in patients with New York Heart Association functional class III or IV heart failure, rest angina, serum creatinine >2.5 mg/dL, left main or 3-vessel CAD, clinical instability, or severe inducible ischemia on stress testing in an infarct zone that is not akinetic or dyskinetic.

5.2.3. Cardiogenic Shock: Recommendations

CLASS I

1. PCI is recommended for patients with acute MI who develop cardiogenic shock and are suitable candidates (384, 421–423). *(Level of Evidence: B)*
2. A hemodynamic support device is recommended for patients with cardiogenic shock after STEMI who do not quickly stabilize with pharmacological therapy (384, 424–427). *(Level of Evidence: B)*

See Online Data Supplement 22 for additional data regarding cardiogenic shock.

Cardiogenic shock is the leading cause of in-hospital mortality complicating STEMI. Revascularization is the only treatment proven to decrease mortality rates (384, 421–423). Although revascularization is almost always accomplished through PCI, selected patients with severe 3-vessel or left main disease can benefit from emergency CABG. Revascu-larization attempts may be futile and not indicated in cases of severe multiorgan failure (427). Patient selection for revascularization is more important in the elderly, but several observational reports demonstrate acceptable outcomes in patients with few comorbidities and a reasonable potential for survival (428–431). Patients who present to hospitals without PCI capability are usually emergently transported to a PCI center, because mortality without transfer is markedly elevated (432).

5.2.3.1. PROCEDURAL CONSIDERATIONS FOR CARDIOGENIC SHOCK. Patients with cardiogenic shock should receive standard pharmacological therapies, including aspirin, a $P2Y_{12}$ receptor antagonist, and anticoagulation (427, 433). Inotropic and vasopressor therapy improves perfusion pressure. Historically, negative inotropes and vasodilators are avoided. IV GP IIb/IIIa inhibitors have been shown to provide benefit in observational studies but not in 1 small RCT (433).

Endotracheal intubation and mechanical ventilation with positive end-expiratory pressure is usually necessary in patients with respiratory failure. Placement of a temporary pacemaker is indicated for patients with bradycardia or high-degree atrioventricular heart block. A pulmonary artery catheter can provide information to dose and titrate inotropes and pressors. Further hemodynamic support is available with IABP counterpulsation or percutaneous LV assist devices, although no data support a reduction in mortality rates (434).

Contrast medium injections should be minimized. Orthogonal angiograms of the left coronary artery and a left anterior oblique angiogram of the right coronary artery are usually sufficient to identify the infarct artery (435). Although most patients undergoing revascularization will receive a stent as part of the procedure, there are conflicting data on the impact of stenting over balloon angioplasty. Some studies reveal lower mortality rates (436–438), whereas others reveal no benefit (439) or higher mortality rates (440). There are no data comparing the choice ofBMS versus DES in cardiogenic shock; however, BMS are often used because compliance with long-term DAPT is often unclear in the emergency setting.

In patients with multivessel disease, revascularization of the noninfarct artery may be necessary to maximize myocardial perfusion. Alternatively, in patients with multivessel disease and particularly left main disease, emergency CABG as a primary reperfusion strategy may be preferred (50, 441). Refractory cardiogenic shock unresponsive to revascularization may necessitate institution of more intensive cardiac support with a ventricular assist device or other hemodynamic support devices to allow for myocardial recovery or subsequent cardiac transplantation in suitable patients.

5.2.4. Revascularization Before Noncardiac Surgery: Recommendations

CLASS IIa

1. For patients who require PCI and are scheduled for elective noncardiac surgery in the subsequent 12 months, a strategy of balloon angioplasty, or BMS implantation followed by 4 to 6 weeks of DAPT, is reasonable (442–448). *(Level of Evidence: B)*
2. For patients with DES who must undergo urgent surgical procedures that mandate the discontinuation of DAPT, it is reasonable to continue aspirin if possible and restart the $P2Y_{12}$ inhibitor as soon as possible in the immediate postoperative period (444). *(Level of Evidence: C)*

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 31

CLASS III: HARM

1. Routine prophylactic coronary revascularization should not be performed in patients with stable CAD before noncardiac surgery (449, 450). *(Level of Evidence: B)*
2. Elective noncardiac surgery should not be performed in the 4 to 6 weeks after balloon angioplasty or BMS implantation or the 12 months after DES implantation in patients in whom the $P2Y_{12}$ inhibitor will need to be discontinued perioperatively (208, 447, 451, 452). *(Level of Evidence: B)*

The 2007 and 2009 ACC/AHA Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery gave detailed recommendations for the evaluation of patients undergoing noncardiac surgery (444). Patients with evidence of ACS should receive standard therapy, including early revascularization, to minimize the risk of adverse events. Patients with known significant left main or 3-vessel CAD who would otherwise benefit from revascularization in terms of survival or symptomatic relief also generally undergo revascularization before elective noncardiac surgery.

Two RCTs (449, 450) found no benefit with routine preoperative revascularization before noncardiac surgery. Noncardiac surgery early after coronary stenting, particularly in the first 4 weeks, is associated with a high risk of stent thrombosis and death (444, 446, 448). When emergency surgery is necessary, the patient should proceed to surgery without prior PCI. When surgery is required within 30 days and coronary revascularization is required before surgery, many clinicians perform balloon angioplasty alone to avoid the need for DAPT. In situations where preoperative revascularization is required and surgery can be deferred for at least 30 days, many clinicians use BMS and discontinue DAPT after 30 days. If surgery is elective and can be deferred for 1 year, most clinicians would consider DES to reduce the long-term risk of restenosis. A dilemma occurs when a patient has undergone PCI and then unexpectedly requires noncardiac surgery. Many patients can undergo surgery on DAPT, where the risk-benefit ratio will favor continued dual antiplatelet inhibition. If it is necessary to hold $P2Y_{12}$ inhibitor therapy, most clinicians will still continue aspirin uninterrupted during the perioperative period if the bleeding risk is not prohibitive. When the risk of delaying surgery or performing surgery while the patient is on DAPT exceeds the risk of stent thrombosis from stopping DAPT, the $P2Y_{12}$ inhibitor is stopped before surgery and resumed as soon as possible afterward. No $P2Y_12$ inhibitor "bridging" strategy (e.g., GP IIb/IIIa inhibitor, antithrombin therapy) has been validated.

5.3. Coronary Stents: Recommendations

CLASS I

1. Before implantation of DES, the interventional cardiologist should discuss with the patient the need for and duration of DAPT and the ability of the patient to comply with and tolerate DAPT (212). *(Level of Evidence: C)*
2. DES are useful as an alternative to BMS to reduce the risk of restenosis in cases in which the risk of restenosis is increased and the patient is likely to be able to tolerate and comply with prolonged DAPT *(Level of Evidence: A for elective PCI* [453,453a,454–456]; *Level of Evidence: C for UA/NSTEMI* (453); *Level of Evidence: A for STEMI* [453,456–459]).
3. Balloon angioplasty or BMS should be used in patients with high bleeding risk, inability to comply with 12 months of DAPT, or anticipated invasive or surgical procedures within the next 12 months, during which time DAPT may be interrupted (208, 460–462). *(Level of Evidence: B)*

CLASS III: HARM

1. PCI with coronary stenting should not be performed if the patient is not likely to be able to tolerate and comply with DAPT (208–211). *(Level of Evidence: B)*
2. DES should not be implanted if the patient is not likely to be able to tolerate and comply with prolonged DAPT or this cannot be determined before stent implantation (208, 460–462). *(Level of Evidence: B)*

Coronary stent implantation is commonly performed during PCI to prevent recoil, abrupt closure, and late restenosis (463, 464). BMS are composed of either stainless steel or cobalt chromium alloys. Because the risk of stent thrombosis is greatest within the first 30 days after implantation, the use of DAPT is required for 30 days after implantation of BMS (208).

In the United States, 4 types of DES are currently approved: sirolimus-eluting stents, paclitaxel-eluting stents, zotarolimus-eluting stents, and everolimus-eluting stents. DES vary according to stent scaffold material and design, drug content, and the polymer used for drug elution; however, several common clinical features are present. First, sirolimus-eluting stents, paclitaxel-eluting stents, and zotarolimus-eluting stents have been demonstrated in RCTs to be associated with a reduced need for repeat revascularization and no increase in death or MI compared with BMS at 4 years' follow-up (465). Everolimus-eluting stents have been demonstrated in RCTs to be associated with a lower need for repeat revascularization than paclitaxel-

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

eluting stents, and, by inference, a lower risk for repeat revascularization than BMS (466, 467), with no increase in death or MI at 2-year follow-up (468). Second, each of these stents is presumed to be associated with delayed healing based on pathologic studies and longer periods of risk for thrombosis compared with BMS and require longer duration of DAPT (469). In the RCTs that led to the U.S. Food and Drug Administration (FDA) approval of these stents, the recommended minimum duration of DAPT therapy was 3 to 6 months. Recently, the consensus of clinical practice has been 12 months of DAPT following DES implantation to avoid late (after 30 days) thrombosis (208), based on observational studies of paclitaxel-eluting stents and sirolimus-eluting stents that indicate lower risk of late stent thrombosis with >6 months of therapy (212). Extending DAPT beyond 1 year is considered reasonable by some practitioners based on observational data analysis (212), but RCTs to determine whether longer DAPT is associated with reduction in stent thrombosis risk have not been completed. Finally, DES therapy is more expensive than BMS. Cost-effectiveness analysis has shown a reduction in total cost associated with DES because of avoidance of repeat procedures, yet it may be reasonable to consider use of BMS in patient subsets in which the risk of restenosis is low (470).

This risk-benefit profile is most favorable for DES over BMS when the risk of restenosis with BMS is high (Table 11). Pooled and meta-analyses have demonstrated that in patients with diabetes, use of DES decreases the risk of restenosis compared with BMS (471, 472). DES may be more appealing for unprotected left main PCI, given the rate and clinical consequences of restenosis in this location (473–475). The risk of stent thrombosis is higher in populations or lesion types excluded from RCTs of DES (e.g., STEMI, smaller arteries [<2.5 mm diameter], longer lesions, bifurcations) (210, 465). Importantly, these features also predict both stent thrombosis (476) and restenosis in BMS (477). The greatest risk of stent thrombosis is within the first year, ranging from 0.7% to 2.0%, depending on patient and lesion complexity. Late stent thrombosis risk after 1 year with DES is observed at a rate of 0.2% to 0.4% per year (210, 478).

Compared with balloon angioplasty, routine BMS implantation during primary PCI decreases risk for target-vessel revascularization and possibly reduces MI rates but does not reduce mortality rates (479). More recent primary PCI studies and meta-analyses have demonstrated lower restenosis rates without increased risk of adverse stent outcome with DES compared with BMS. Although stent thrombosis rates in trials ofSTEMI are higher than in trials of elective PCI, the rates of stent thrombosis are not higher with DES compared with BMS in STEMI (453, 456–459).

TABLE 11. Clinical Situations Associated With DES or BMS Selection Preference

DES Generally Preferred Over BMS (Efficacy Considerations)	BMS Preferred Over DES (Safety Considerations)
• Left main disease	• Unable to tolerate or comply with DAPT
• Small vessels	• Anticipated surgery requiring discontinuation of DAPT within 12 mo
• In-stent restenosis	• High risk of bleeding
• Bifurcations	
• Diabetes	
• Long lesions	
• Multiple lesions	
• Saphenous vein grafts	

BMS indicates bare-mental stent(s); DAPT, dual antiplatelet therapy; and DES, drug-eluting stent(s).

The greatest risk for DES thrombosis is early discontinuation of DAPT (208, 460–462). It is therefore important to determine that the patient will likely be able to tolerate and comply with DAPT before implantation of DES. Therefore, DES should not be used in the presence of financial barriers to continuing prolonged DAPT, social barriers that may limit patient compliance, or medical issues involving bleeding risks or the need for invasive or surgical procedures in the following year that would interrupt antiplatelet therapy. The need for use of long-term warfarin and the associated increased risk ofbleeding with long-term "triple therapy" is also a consideration in deciding on DES versus BMS (480).

Patients implanted with most contemporary coronary stents can undergo magnetic resonance imaging (MRI) examination any time after implantation (481, 482). The effect of the MRI examination on heating of the drug or polymer coating used in DES is unknown. There is no indication for antibiotic prophylaxis before dental or invasive procedures in patients with coronary stents (483).

5.4. Adjunctive Diagnostic Devices

5.4.1. FFR: Recommendation

CLASS IIa

1. FFR is reasonable to assess angiographic intermediate coronary lesions (50% to 70% diameter stenosis) and can be useful for guiding revascularization decisions in patients with SIHD (12, 97, 484–486). *(Level of Evidence: A)*

See Online Data Supplement 23 for additional data regarding FFR.

The limitations of coronary angiography for determination of lesion severity have been well described. Angiography may under- or overestimate lesion stenosis. Various physiologic measurements can be made in the catheterization laboratory, including

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

coronary flow reserve and FFR. The correlation of ischemia on stress testing with FFR values of <0.75 has been established in numerous comparative studies with high sensitivity (88%), specificity (100%), positive predictive value (100%), and overall accuracy (93%) (487). The 5-year outcomes for patients with medical therapy based on an FFR >0.75 were superior compared with PCI in the DEFER (Deferral Versus Performance of Balloon Angioplasty in Patients Without Documented Ischemia) study (485). The FAME (Fractional Flow Reserve Versus Angiography for Multivessel Evaluation) study identified the benefit for deferring PCI in patients with multivessel disease and lesion FFR >0.80, with reduced rates of cardiac events at both 1 and 2 years (97, 486). Whereas both FFR and IVUS have been used for assessment of intermediate angiographic stenosis with favorable outcomes, FFR may reduce the need for revascularization when compared with IVUS (488). Although IVUS is often considered in the assessment ofequivocal left main stenosis, FFR may be similarly effective (484).

5.4.2. IVUS: Recommendations

CLASS IIa

1. IVUS is reasonable for the assessment of angiographically indeterminant left main CAD (489–491). *(Level of Evidence: B)*
2. IVUS and coronary angiography are reasonable 4 to 6 weeks and 1 year after cardiac transplantation to exclude donor CAD, detect rapidly progressive cardiac allograft vasculopathy, and provide prognostic information (492–494). *(Level of Evidence: B)*
3. IVUS is reasonable to determine the mechanism of stent restenosis (495). *(Level of Evidence: C)*

CLASS IIb

1. IVUS may be reasonable for the assessment of non-left main coronary arteries with angiographically intermediate coronary stenoses (50% to 70% diameter stenosis) (489, 496, 497). *(Level of Evidence: B)*
2. IVUS may be considered for guidance of coronary stent implantation, particularly in cases of left main coronary artery stenting (490, 495, 498). *(Level of Evidence: B)*
3. IVUS may be reasonable to determine the mechanism of stent thrombosis (495). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. IVUS for routine lesion assessment is not recommended when revascularization with PCI or CABG is not being contemplated. *(Level of Evidence: C)*

IVUS provides a unique coronary artery assessment of lesion characteristics, minimal and maximal lumen diameters, cross-sectional area, and plaque area. Diagnostic uses for IVUS include the assessment of angiographic indeterminant coronary artery stenoses, determination of the mechanism of stent restenosis or thrombosis, and postcardiac transplantation surveillance of CAD (488, 490–492, 499). For left main coronary artery stenoses, a minimal lumen diameter of <2.8 mm or a minimal lumen area of <6mm^2 suggests a physiologically significant lesion for which patients may benefit from revascularization. A minimal lumen area >7.5 mm^2 suggests that revascularization may be safely deferred (490). A minimal lumen area between 6 and 7.5 mm^2 requires further physiological assessment, such as measurement of FFR (487, 500). For non-left main stenoses, minimal lumen diameter >2.0 mm and minimal lumen area > 4.0 mm^2 correlate with low event rates (489). However, in smaller-diameter arteries (minimal lumen area <3.0 mm^2), measurement of FFR may more accurately reflect a significant stenosis (488). Studies correlating IVUS measures with ischemia have not specified the size of coronary arteries for which such correlations are valid (488, 489, 497).

IVUS assessment after stent thrombosis may serve to identify stent underexpansion or malapposition (499). IVUS is superior to angiography in the early detection of the diffuse, immune-mediated, cardiac allograft vasculopathy; recommendations about the use of IVUS for this purpose were published in 2010 by the International Society of Heart and Lung Transplantation (492). Whereas IVUS has been an important research tool in interventional cardiology, most clinical studies of IVUS have not been able to demonstrate that its routine use results in a reduction of MACE or restenosis rates (498, 501, 502). IVUS has been inappropriately used in clinical practice to justify implanting stents in mildly diseased segments that may require no intervention (503).

5.4.3. Optical Coherence Tomography. Compared with IVUS, optical coherence tomography has greater resolution (10 to 20 micronmeter axially) but more limited depth of imaging (1 to 1.5 mm) (504, 505). Unlike IVUS, optical coherence tomography requires that the artery be perfused with saline solution or crystalloid during image acquisition and therefore does not permit imaging of ostial lesions. Clinical studies have shown low optical coherence tomography complication rates (506, 507), similar to those of IVUS (508). The excellent resolution of optical coherence tomography permits detailed in vivo 2-dimensional imaging of plaque morphological characteristics (e.g., calcification, lipid, thrombus, fibrous cap thickness, and plaque ulceration or rupture) (508–510) and evaluation of the arterial response to stent implantation (e.g., stent strut neointimal thickness and apposition) (511–513) and

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

may be of value in clinical research. The appropriate role for optical coherence tomography in routine clinical decision making has not been established.

5.5. Adjunctive Therapeutic Devices

5.5.1. Coronary Atherectomy: Recommendations

CLASS IIa

1. Rotational atherectomy is reasonable for fibrotic or heavily calcified lesions that might not be crossed by a balloon catheter or adequately dilated before stent implantation (514, 515). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Rotational atherectomy should not be performed routinely for de novo lesions or in-stent restenosis (516–519). *(Level of Evidence: A)*

Rotational atherectomy in RCTs was associated with higher rates of MACE at 30 days and no reduction in restenosis. It has a limited role in facilitating the dilation or stenting of lesions that cannot be crossed or expanded with PCI (520, 521). Devices for directional coronary atherectomy are no longer marketed in the United States.

5.5.2. Thrombectomy: Recommendation

CLASS IIa

1. Aspiration thrombectomy is reasonable for patients undergoing primary PCI (522–524). *(Level of Evidence: B)*

The benefit of thrombectomy in patients with STEMI appears to be dependent on the type of thrombectomy technique used (522–526). No clinical benefit for routine rheolytic thrombectomy (AngioJet device, MEDRAD Interventional, Minneapolis, MN and Pittsburgh, PA) has been demonstrated in primary PCI (524–526). Two RCTs (522, 523) and a meta-analysis (524) support the use of manual aspiration thrombectomy during primary PCI to improve microvascular reperfusion and decrease MACE. It is not known whether a strategy of selective thrombus aspiration in patients with a large thrombus burden might be equivalent to routine thrombus aspiration.

5.5.3. Laser Angioplasty: Recommendations

CLASS IIb

1. Laser angioplasty might be considered for fibrotic or moderately calcified lesions that cannot be crossed or dilated with conventional balloon angioplasty (527). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Laser angioplasty should not be used routinely during PCI (516, 518, 528). *(Level of Evidence: A)*

RCTs of laser angioplasty have not demonstrated improved clinical or angiographic PCI outcomes, although some practitioners think that laser angioplasty may be of use in the treatment of lesions that are difficult to dilate with balloon angioplasty (527).

5.5.4. Cutting Balloon Angioplasty: Recommendations

CLASS IIb

1. Cutting balloon angioplasty might be considered to avoid slippage-induced coronary artery trauma during PCI for in-stent restenosis or ostial lesions in side branches (529). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Cutting balloon angioplasty should not be performed routinely during PCI (516, 529, 530). *(Level of Evidence: A)*

Although some small, single-center trials have suggested that cutting balloon angioplasty was more efficacious than balloon angioplasty, it was not found to be safer or more effective in several large trials (516, 529, 531). When balloon dilation is required for in-stent restenosis, however, cutting balloons are less likely to slip and may offer a technical advantage over conventional balloons (529). Scoring balloons have been used by some cardiologists as an alternative to cutting balloons, but no RCTs have been reported (531).

5.5.5. Embolic Protection Devices: Recommendation

CLASS I

1. Embolic protection devices (EPDs) should be used during saphenous vein graft (SVG) PCI when technically feasible (532–535). *(Level of Evidence: B)*

The incidence of MACE doubles in SVG PCI compared with native-artery PCI (536). A distal balloon occlusion EPD decreased the 30-day composite outcome of death, MI, emergency CABG, or target-lesion revascularization (9.6% versus 16.5%) in the only RCT (532). Subsequent noninferiority comparisons have demonstrated similar benefit with proximal occlusion and distal filter EPDs, with benefit limited to reduction in periprocedural MI (534, 535) (Section 5.10). Distal EPDs do not improve survival or reinfarction rates in patients undergoing native-artery PCI (524, 537).

5.6. Percutaneous Hemodynamic Support Devices: Recommendation

CLASS IIb

1. Elective insertion of an appropriate hemodynamic support device as an adjunct to PCI may be

reasonable in carefully selected high-risk patients. *(Level of Evidence: C)*

IABP counterpulsation is frequently used as an adjunct to PCI in hemodynamically unstable patients (538, 539). In single-center series, the routine prophylactic use of IABP during PCI in high-risk patients was associated with lower mortality and fewer major complications compared with rescue use of IABP (540, 541). In the only RCT in high-risk PCI patients (BCIS-1 [Balloon Pump-Assisted Coronary Intervention Study]) (542), there was no difference in the primary composite outcome between routine and provisional use of IABP. There were also no differences in major secondary endpoints except major procedural complications (e.g., prolonged hypotension, ventricular tachycardia/ fibrillation, cardiopulmonary arrest), which were lower in the routine IABP group. Bleeding and access site complication rates tended to be higher in the routine IABP group. The "bailout" rate of IABP insertion in the provisional IABP group was 12%, mostly for procedural hypotension (542). A meta-analysis of IABP therapy in patients with STEMI did not show improved outcomes with the use of IABP (434).

The Impella Recover LP 2.5 System (Abiomed, Aachen, Germany/Danvers, Massachusetts) is a 12.5 Fr catheter that is inserted percutaneously through a 13 Fr femoral artery sheath and placed across the aortic valve into the left ventricle, through which a transaxial blood pump provides flows of up to 2.5 L/min. This has been used in patients with cardiogenic shock (543, 544) as well as elective PCI (545). The hemodynamic effects of the Impella 2.5 have been studied in high-risk PCI patients, demonstrating beneficial LV unloading effect (decreased end-diastolic pressure and wall stress) with no change in global or systolic LV function (546). The PROTECT I (A Prospective Feasibility Trial Investigating the Use of the IMPELLA Recover LP 2.5 System in Patients Undergoing High-Risk PCI) trial in 20 patients undergoing high-risk PCI with the Impella 2.5 system concluded that this device was safe, easy to implant, and hemodynamically effective (547). The Europella Registry included 144 patients undergoing high-risk PCI and reported the safety, feasibility, and potential usefulness of the device and that RCTs were warranted (548). The randomized PROTECT II (A Prospective, Multicenter, Randomized Controlled Trial of the IMPELLA Recover LP 2.5 System Versus Intra Aortic Balloon Pump in Patients Undergoing Non Emergent High Risk PCI) trial, which was designed to demonstrate superiority ofImpella over IABP in terms of 1-month adverse events, was halted for futility after interim analysis of study results (549).

The TandemHeart (CardiacAssist, Inc, Pittsburgh, PA) is a left atrial to aorta catheter-based system that includes a centrifugal blood pump providing flows of up to 4 L/min. This device uses a 21 Fr cannula percutaneously inserted into the femoral vein for transseptal access of the left atrium with a 15 Fr catheter placed in the contralateral femoral artery and positioned above the aortic bifurcation. An extracorporeal pump then returns oxygenated blood from the left atrium to the arterial system, thereby unloading the left ventricle (550, 551). The hemodynamic effects have been studied in patients undergoing high-risk PCI (552). Several small studies have addressed the clinical efficacy of the TandemHeart in high-risk patients undergoing PCI (551, 553–556). In a single-center report of 68 patients undergoing high-risk PCI using either TandemHeart or Impella Recover 2.5, success rates (>90%) and vascular complications (7%) were similar (553).

High-risk patients may include those undergoing unprotected left main or last-remaining-conduit PCI, those with severely depressed EF undergoing PCI of a vessel supplying a large territory, and/or those with cardiogenic shock. Patient risk, hemodynamic support, ease of application/ removal, and operator and laboratory expertise are all factors involved in consideration of use of these devices. With devices that require large cannula insertion, the risk of vascular injury and related complications are important considerations regarding necessity and choice of device.

5.7. Interventional Pharmacotherapy

5.7.1. Procedural Sedation. The term *conscious sedation* is falling out of favor with the recognition that there is a spectrum of procedural sedation levels. Most patients undergoing PCI fall under the definition of either minimal sedation (anxiolysis) or moderate sedation (depressed consciousness with the ability to respond purposefully to verbal commands) (557). Nonetheless, an underlying principle of procedural sedation is that the physician should be prepared to manage one level of sedation deeper than the level intended. Thus, cardiologists should be cognizant of the principles of managing deep sedation (depressed consciousness without easy arousal that may require assistance in maintaining airway patency or spontaneous ventilation).

A full review of procedural sedation is beyond the scope of this document, but practice guidelines for sedation and analgesia by nonanesthesiologists, along with The Joint Commission standards, provides a reasonable framework. These guidelines outline several general principles (558, 559). Before the procedure the patient should be assessed for predictors of difficult

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

intubation or a history of prior difficult intubation. The patient should be monitored by someone dedicated to observing the level and effects of sedation. Level of consciousness, respiratory rate, blood pressure, cardiac rhythm, and oxygen saturation by pulse oximetry should be monitored. Available equipment should include a high-flow oxygen source, suction, airway management equipment, a defibrillator, resuscitation drugs, and reversal agents appropriate for the drugs being used. A free-flowing IV line should be established. Supplemental oxygen is usually administered, even in the absence of preexisting hypoxia, to provide a margin of safety.

Agents used for sedation are best given in incremental doses, allowing adequate time for the development and assessment of peak effect. The most commonly used agents are listed in Appendix 4F.

5.7.2. Oral Antiplatelet Therapy: Recommendations

CLASS I

1. Patients already taking daily aspirin therapy should take 81 mg to 325 mg before PCI (301–304). *(Level of Evidence: B)*
2. Patients not on aspirin therapy should be given non-enteric aspirin 325 mg before PCI (301, 303, 304). *(Level of Evidence: B)*
3. After PCI, use of aspirin should be continued indefinitely (560–563). *(Level of Evidence: A)*
4. A loading dose of a $P2Y_{12}$ receptor inhibitor should be given to patients undergoing PCI with stenting (564–568) *(Level of Evidence: A)*. Options include
   a. Clopidogrel 600 mg (ACS and non-ACS patients) (564–566) *(Level of Evidence: B)*
   b. Prasugrel 60 mg (ACS patients) (567) *(Level of Evidence: B)*
   c. Ticagrelor 180 mg (ACS patients) (568) *(Level of Evidence: B)*
5. The loading dose of clopidogrel for patients undergoing PCI after fibrinolytic therapy should be 300 mg within 24 hours and 600 mg more than 24 hours after receiving fibrinolytic therapy (565, 569). *(Level of Evidence: C)*
6. Patients should be counseled on the need for and risks of DAPT before placement of intracoronary stents, especially DES, and alternative therapies should be pursued if patients are unwilling or unable to comply with the recommended duration of DAPT (208). *(Level of Evidence: C)*
7. The duration of $P2Y_{12}$ inhibitor therapy after stent implantation should generally be as follows:
   a. In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ inhibitor therapy should be given for at least 12 months. Options include clopidogrel 75 mg daily (570), prasugrel 10 mg daily (567), and ticagrelor 90 mg twice daily (568). *(Level of Evidence: B)*
   b. In patients receiving DES for a non-ACS indication, clopidogrel 75 mg daily should be given for at least 12 months if patients are not at high risk of bleeding (208, 212, 571). *(Level of Evidence: B)*
   c. In patients receiving BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks) (208, 572). *(Level of Evidence: B)*

CLASS IIa

1. After PCI, it is reasonable to use aspirin 81 mg per day in preference to higher maintenance doses (302, 573–576). *(Level of Evidence: B)*
2. If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of $P2Y_{12}$ inhibitor therapy after stent implantation, earlier discontinuation (e.g., <12 months) of $P2Y_{12}$ inhibitor therapy is reasonable. *(Level of Evidence: C)*

CLASS IIb

1. Continuation of DAPT beyond 12 months may be considered in patients undergoing DES implantation (567, 568). *(Level of Evidence: C)*

CLASS III: HARM

1. Prasugrel should not be administered to patients with a prior history of stroke or transient ischemic attack (567). *(Level of Evidence: B)*

Aspirin reduces the frequency of ischemic complications after PCI. Although the minimum effective aspirin dosage in the setting of PCI has not been established, aspirin 325 mg given at least 2 hours, and preferably 24 hours, before PCI is recommended (302, 303), after which aspirin 81 mg daily should be continued indefinitely.

Several investigations have explored various loading doses of clopidogrel before or during PCI. Compared with a 300-mg loading dose, doses of either 600 mg or 900 mg achieve greater degrees of platelet inhibition with fewer low responders (577). A meta-analysis of 7 studies that included 25,383 patients undergoing PCI demonstrated that intensified loading of clopidogrel with 600 mg reduces the rate of MACE without an increase in major bleeding compared with 300 mg (578). Another study suggested that a 600-mg loading dose of clopidogrel is associated with improvements in procedural angiographic endpoints and 1-year clinical outcomes in patients with STEMI who undergo

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 37

primary PCI compared with a 300-mg dose (579). There is no benefit with increasing the loading dose to 900 mg compared with 600 mg (577). Clopidogrel 75 mg daily should be given for a minimum of 4 weeks after balloon angioplasty or BMS implantation (a minimum of 2 weeks if increased bleeding risk is present) (580) and for at least 12 months after DES implantation (unless the risk of bleeding outweighs the anticipated benefit). Patients should be counseled on the need for and risks of DAPT before stent implantation, especially DES implantation, and alternative therapies pursued (BMS or balloon angioplasty) if they are unwilling or unable to comply with the recommended duration of DAPT.

The efficacy of clopidogrel pretreatment remains controversial. Although some studies have suggested that pretreatment with clopidogrel is associated with decreased platelet aggregation and a significantly lower incidence of periprocedural MI after elective PCI, others have suggested no benefit to pretreatment compared with administration of the drug in the catheterization laboratory (572, 581, 582).

When prasugrel was compared with clopidogrel in patients with ACS in TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis In Myocardial Infarction), prasugrel was associated with a significant 2.2% reduction in absolute risk and a 19% reduction in relative risk in the composite endpoint of cardiovascular death, nonfatal MI, or nonfatal stroke, and a significant increase in the rate of TIMI major hemorrhage (1.8% versus 2.4%) (567). Prasugrel is contraindicated in patients with a history of transient ischemic attack or stroke. Patients weighing <60 kg have an increased risk of bleeding on the 10 mg daily maintenance dose. The package insert suggests that consideration should be given to lowering the maintenance dose to 5 mg daily, although the effectiveness and safety of the 5-mg dose has not been studied. Prasugrel is not recommended for patients >75 years of age because of the increased risk of fatal and intracranial bleeding and lack of benefit, except in patients with diabetes or a history of prior MI. Prasugrel should not be started in patients likely to undergo urgent CABG. Prasugrel has not been studied in elective PCI, and thus no recommendation can be made regarding its use in this clinical setting.

Ticagrelor reversibly binds the $P2Y_{12}$ receptor. Unlike clopidogrel or prasugrel, ticagrelor is not a thienopyridine. It also does not require metabolic conversion to an active metabolite. Compared with clopidogrel in patients with ACS in the PLATO (Platelet Inhibition and Patient Outcomes) trial, ticagrelor was associated with a significant 1.9% reduction in absolute risk and a 16% reduction in relative risk in the primary composite endpoint of vascular death, nonfatal MI, or nonfatal stroke (568). Importantly, a significant reduction in vascular mortality and all-cause mortality was observed. Although CABG-related bleeding was not significantly increased with ticagrelor compared with clopidogrel, a significantly greater incidence of major bleeding was observed in patients not undergoing CABG. Ticagrelor was associated with higher rates of transient dyspnea and bradycardia compared with clopidogrel, although only a very small percentage of patients discontinued the study drug because of dyspnea. Based on post hoc analysis of the PLATO study, specifically the results in the U.S. patient cohort, a black box warning states that maintenance doses of aspirin above 100 mg reduce the effectiveness of ticagrelor and should be avoided. After any initial dose, ticagrelor should be used with aspirin 75 mg to 100 mg per day (583). Given the twice-daily dosing and reversible nature of the drug, patient compliance may be a particularly important issue to consider and emphasize. Ticagrelor has not been studied in elective PCI or in patients who received fibrinolytic therapy; thus, no recommendations about its use in these clinical settings can be made.

5.7.3. IV Antiplatelet Therapy: Recommendations STEMI

CLASS IIa

1. In patients undergoing primary PCI treated with UFH, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban), whether or not patients were pretreated with clopidogrel (584–590). *(For GP IIb/IIIa inhibitor administration in patients not pretreated with clopidogrel, Level of Evidence: A; for GP IIb/IIIa inhibitor administration in patients pretreated with clopidogrel, Level of Evidence: C)*

CLASS IIb

1. In patients undergoing primary PCI with abciximab, it may be reasonable to administer intracoronary abciximab (589, 591–604). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. Routine precatheterization laboratory (e.g., ambulance or emergency department) administration of GP IIb/IIIa inhibitors as part of an upstream strategy for patients with STEMI undergoing PCI is not beneficial (605–612). *(Level of Evidence: B)*

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

UA/NSTEMI

CLASS I

1. In UA/NSTEMI patients with high-risk features (e.g., elevated tro-ponin level) not treated with bivalirudin and not adequately pre-treated with clopidogrel, it is useful at the time of PCI to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) in patients treated with UFH (613–618). *(Level of Evidence: A)*

CLASS IIa

1. In UA/NSTEMI patients with high-risk features (e.g., elevated troponin level) treated with UFH and adequately pretreated with clopidogrel, it is reasonable at the time of PCI to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) (616, 619). *(Level of Evidence: B)*

SIHD

CLASS IIa

1. In patients undergoing elective PCI treated with UFH and not pretreated with clopidogrel, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) (619–621). *(Level of Evidence: B)*

CLASS IIb

1. In patients undergoing elective PCI with stent implantation treated with UFH and adequately pretreated with clopidogrel, it might be reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) (619, 622–624). *(Level of Evidence: B)*

See Online Data Supplement 24 for additional data regarding IV antiplatelet therapy.

In the era before DAPT, trials of adequately dosed GP IIb/IIIa inhibitors in patients undergoing balloon angioplasty and coronary stent implantation demonstrated a reduction in the incidence of composite ischemic events with GP IIb/IIIa treatment, primarily through a reduction of enzymatically defined MI (613, 615, 618, 620, 621). Earlier RCTs of GP IIb/IIIa inhibitors were generally conducted in patients treated with UFH. In some trials, use of GP IIb/IIIa inhibitors are associated with some increased bleeding risk, and trials of these agents have generally excluded patients at high risk of bleeding (e.g., coagulopathy) (584, 587–589, 613–618, 620–626). Thus, recommendations about use of GP IIb/IIIa inhibitors are best construed as applying to those patients not at high risk of bleeding complications. Abciximab, double-bolus eptifibatide (180 mcg/kg bolus followed 10 minutes later by a second 180 mcg/kg bolus), and high-bolus dose tirofiban (25 mcg/kg) all result in a high degree of platelet inhibition (627–629), have been demonstrated to reduce ischemic complications in patients undergoing PCI (608, 609, 613, 615, 618–621), and appear to lead to comparable angiographic and clinical outcomes (630, 631).

Trials of GP IIb/IIIa inhibitors in the setting of STEMI and primary PCI were conducted in the era before routine stenting and DAPT. The results of these and more recent trials, as well as several meta-analyses, have yielded mixed results (584–590). Therefore, it is reasonable to administer GP IIb/IIIa inhibitors in patients with STEMI undergoing PCI, although these agents cannot be definitively recommended as routine therapy. These agents might provide more benefit in selective use, such as in patients with large anterior MI and/or large thrombus burden. Trials of precatheterization laboratory (e.g., ambulance or emergency room) administered GP IIb/IIIa inhibitors in patients with STEMI undergoing PCI, with or without fibrinolytic therapy, have generally shown no clinical benefit, and GP IIb/IIIa inhibitor use in this setting may be associated with an increased risk of bleeding (605–610, 612). Studies of intracoronary GP IIb/IIIa inhibitor administration (predominantly using abciximab) consist of several small RCTs, retrospective analyses, retrospective and prospective registries, cohort analyses, and case reports. Although most of these published studies have reported some benefit of intracoronary administration in terms of acute angiographic parameters, infarct size, left ventricle myocardial salvage, and composite clinical endpoints, several other studies have not detected any benefit with intracoronary administration (589, 591–604).

Trials of GP IIb/IIIa inhibitors in patients with UA/NSTEMI undergoing PCI demonstrated reduced ischemic outcomes, particularly in those with high-risk features such as positive biomarkers. Most trials were conducted in a prior PCI era and without $P2Y_{12}$ inhibitor pretreatment (613, 615, 618, 632, 633), although several trials have also demonstrated benefit in patients with high-risk features pretreated with clopidogrel (616, 619). In most older studies of stable patients undergoing balloon angioplasty or coronary stenting, treatment with GP IIb/IIIa inhibitors resulted in a reduction of composite ischemic events, primarily enzymatically defined MI (613–618, 620, 621, 634, 635). More contemporary trials of patients pretreated with a thienopyridine have not demonstrated any benefit with GP IIb/IIIa inhibitor therapy in patients with stable symptoms undergoing elective PCI (619, 622–624).

Drug	Patient Has Received Prior Anticoagulant Therapy	Patient Has Not Received Prior Anticoagulant Therapy
UFH	• IV GPI planned: additional UFH as needed (e.g., 2,000 to 5,000 U) to achieve an ACT of 200 to 250 s • No IV GPI planned: additional UFH as needed (e.g., 2,000 to 5,000 U) to achieve an ACT of 250 to 300 s for HemoTec, 300 to 350 s for Hemochron	• IV GPI planned: 50 to 70 U/kg bolus to achieve an ACT of 200 to 250 s • No IV GPI planned: 70 to 100 U/kg bolus to achieve target ACT of 250 to 300 s for HemoTec, 300 to 350 s for Hemochron
Enoxaparin	• For prior treatment with enoxaparin, if the last SC dose was administered 8 to 12 h earlier or if only 1 SC dose of enoxaparin has been administered, an IV dose of 0.3 mg/kg of enoxaparin should be given. • If the last SC dose was administered within the prior 8 h, no additional enoxaparin should be given.	0.5 to 0.75 mg/kg IV bolus
Bivalirudin	For patients who have received UFH, wait 30 min, then give 0.75 mg/kg IV bolus, then 1.75 mg/kg per h IV infusion.	0.75 mg/kg bolus, 1.75 mg/kg per h IV infusion
Fondaparinux	For prior treatment with fondaparinux, administer additional IV treatment with an anticoagulant possessing anti-IIa activity, taking into account whether GPI receptor antagonists have been administered.	N/A
Argatroban	200 mcg/kg IV bolus, then 15 mcg/kg per min IV infusion	350 mcg/kg bolus, then 15 mcg/kg per min IV infusion

ACT indicates activated clotting time; IV, intravenous; GPI, glycoprotein inhibitor; N/A, not applicable; PCI, percutaneous coronary intervention; SC, subcutaneous; and UFH, unfractionated heparin.

5.7.4. Anticoagulant Therapy

5.7.4.1. USE OF PARENTERAL ANTICOAGULANTS DURING PCI: RECOMMENDATION

CLASS I

1. An anticoagulant should be administered to patients undergoing PCI. *(Level of Evidence: C)*

Anticoagulant therapy prevents thrombus formation at the site of arterial injury, on the coronary guidewire, and in the catheters used for PCI (8). With rare exceptions (636), all PCI studies have used some form of anticoagulant. It is the consensus of the writing committee that PCI be performed with the use of some form of anticoagulant therapy. Suggested dosing regimens of parenteral agents used in PCI are given in Table 12. Recommendations for antiplatelet and antithrombin pharmacotherapy in PCI are given in Table 13.

5.7.4.2. UFH: RECOMMENDATION

CLASS I

1. Administration of IV UFH is useful in patients undergoing PCI. *(Level of Evidence: C)*

As the only anticoagulant available for PCI for many years, UFH became the standard of care by default (8). The dose of UFH for PCI has been based on empiricism and experience from RCTs. Suggested UFH dosing regimens are given in Table 12. When UFH is used during PCI, most cardiologists assess the degree of anticoagulation by measuring the activated clotting time. Although measurements are useful to show that an anti-IIa anticoagulant has been given, the value of the activated clotting time in current practice has been questioned. Although studies in the balloon angioplasty era did demonstrate a relationship between activated clotting time levels and ischemic complications (653–655), more recent analyses from the coronary stent era have not found a clear relationship between activated clotting time and outcomes (349, 656, 657). There may, however, be a modest relation between bleeding and activated clotting time levels (349, 657). In addition, not only are there differences between activated clotting time levels measured by Hemochron and HemoTec devices, but both devices have less than optimal precision (658). Thus, although traditional target activated clotting time levels are included in this document, the utility of measured activated clotting time levels in current practice should be considered uncertain.

Most cardiologists remove femoral sheaths when the activated clotting time falls to <150 to 180 seconds or when the activated partial thromboplastin time falls to <50 seconds. Full-dose anticoagulation is no longer used after successful PCI procedures. Almost all large clinical trials have enrolled patients who underwent transfemoral PCI, but recent small studies assessing the transradial approach have used similar doses of UFH (659) and similar activated clotting time target levels (660).

5.7.4.3. ENOXAPARIN: RECOMMENDATIONS

CLASS I

1. An additional dose of 0.3 mg/kg IV enoxaparin should be administered at the time of PCI to patients who have received fewer than 2 therapeutic

TABLE 13. Recommendations for Antiplatelet and Antithrombin Pharmacotherapy at the Time of PCI

	COR	LOE	References	Relevant Caveats/Comments
Oral antiplatelet agents				
Aspirin	I	B	(301–304, 560–563)	N/A
$P2Y_{12}$ inhibitors	I	A	(564–568)	• A loading dose of a $P2Y_{12}$ inhibitor should be given to patients undergoing PCI with stenting.
• Clopidogrel	I	B	(564–566)	• 600-mg loading dose now recommended.
• Prasugrel	I	B	(567)	• Contraindicated in patients with prior TIA/CVA: ***Class III: Harm; LOE: B.*** • Generally not recommended in patients >75 y of age (Section 5.7.2). • Consideration of using a lower maintenance dose in patients weighing <60 kg suggested by FDA (Section 5.7.2).
• Ticagrelor	I	B	(568)	• Issues of patient compliance may be especially important.
GP IIb/IIIa inhibitors (abciximab, double-bolus eptifibatide, high-bolus dose tirofiban)				
• No clopidogrel pretreatment	STEMI: IIa	A	(584–590)	• UA/NSTEMI recommendation applies to those with high-risk features. • GPI use in STEMI may be most appropriate in those with large anterior MI and/or large thrombus burden. • IC abciximab administration in STEMI: ***Class IIb; LOE: B.*** • Precatheterization laboratory GPI administration in STEMI: ***Class III: No Benefit; LOE: B.*** • Recommendations apply to those not at high risk for bleeding complications.
	UA/NSTEMI: I	A	(613–618)	
	SIHD: IIa	B	(619–621)	
• Clopidogrel pretreatment	STEMI: IIa	C	(584–590)	
	UA/NSTEMI: IIa	B	(616, 619)	
	SIHD: IIb	B	(619, 622–624)	
Antithrombin agents				
UFH	I	C	N/A	• Dosing based on whether or not GPI was administered.
Bivalirudin	I	B	(625, 637–645)	• Lower bleeding rates associated with bivalirudin are mitigated when used concomitantly with a GPI.
Enoxaparin	IIb	B	(646–650)	• Recommendations apply to administration of IV enoxaparin at the time of PCI for those who have not received prior antithrombin therapy or who have received "upstream" SC enoxaparin therapy for UA/NSTEMI. • An additional dose of 0.3 mg/kg IV enoxaparin should be administered at the time of PCI to patients who have received <2 therapeutic SC doses (e.g., 1 mg/kg) or received the last SC enoxaparin dose 8 to 12 h before PCI: ***Class I; LOE: B.*** • Patients treated with SC enoxaparin within 12 h of PCI should not receive additional treatment with UFH during PCI ("stacking"): ***Class III: Harm; LOE: B.***
Anti-Xa inhibitors				
Fondaparinux	III: Harm	C	(651, 652)	• PCI should not be performed with fondaparinux as the sole antithrombin agent in patients treated with upstream fondaparinux. An additional anticoagulant with anti-IIa activity should be administered.

ACT indicates activated clotting time; COR, class of recommendation; CVA, cerebrovascular accident; FDA, U.S. Food and Drug Administration; GP, glycoprotein; GPI, glycoprotein IIb/IIIa inhibitor; IC, intracoronary; IV, intravenous; LOE, level of evidence; MI, myocardial infarction; N/A, not applicable; PCI, percutaneous coronary intervention; SC, subcutaneous; SIHD, stable ischemic heart disease; STEMI, ST-elevation myocardial infarction; TIA, transient ischemic attack; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; and UFH, unfractionated heparin.

subcutaneous doses (e.g., 1 mg/kg) or received the last subcutaneous enoxaparin dose 8 to 12 hours before PCI (649, 661–664). *(Level of Evidence: B)*

CLASS IIb

1. Performance of PCI with enoxaparin may be reasonable in patients either treated with "upstream" subcutaneous enoxaparin for UA/ NSTEMI or who have not received prior antithrombin therapy and are administered IV enoxaparin at the time of PCI (646–650). *(Level of Evidence: B)*

CLASS III: HARM

1. UFH should not be given to patients already receiving therapeutic subcutaneous enoxaparin (649, 665). *(Level of Evidence: B)*

Trials of enoxaparin relevant to PCI include both studies in which patients with UA/NSTEMI were started on upstream subcutaneous enoxaparin therapy that was continued up to the time of PCI and trials in which patients who had received no prior antithrombin therapy were treated with IV enoxaparin at the time of PCI (646–650, 661–663, 666). In the SYNERGY

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

(Superior Yield of the New strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial, there was an increased incidence of bleeding in those treated with upstream enoxaparin, later attributed at least in part to the fact that some patients being treated with enoxaparin were also administered UFH at the time of PCI (so-called "stacking") (649, 665). Almost all patients undergoing elective PCI who are administered enoxaparin (0.5 mg/kg IV) will have a peak anti-Xa level > 0.5 IU/mL (647). Most clinical studies have used a regimen of 0.5 to 0.75 mg IV (667). Several studies have used this regimen in elective patients and those with STEMI (646). Patients who have received multiple doses of subcutaneously administered enoxaparin who undergo PCI within 8 hours of the last subcutaneous dose generally have adequate degrees ofanticoagulation to undergo PCI, but the degree of anticoagulation may diminish in the 8- to 12-hour period after the last subcutaneous dose. In such patients, as well as in patients who have received only 1 subcutaneous dose of enoxaparin, the addition of enoxaparin (0.3 mg/kg IV) at the time of PCI provides an additional degree of anticoagulation and has become standard practice (648, 661–664). Patients who undergo PCI >12 hours after the last subcutaneous dose are usually treated with full-dose de novo anticoagulation using an established regimen (e.g., full-dose UFH or bivalirudin).

5.7.4.4. BIVALIRUDIN AND ARGATROBAN: RECOMMENDATIONS

CLASS I

1. For patients undergoing PCI, bivalirudin is useful as an anticoagulant with or without prior treatment with UFH (625, 637–645). *(Level of Evidence: B)*
2. For patients with heparin-induced thrombocytopenia, it is recommended that bivalirudin or argatroban be used to replace UFH (668, 669). *(Level of Evidence: B)*

Bivalirudin is being increasingly used in clinical practice (670) as evidence emerges from clinical trials across the spectrum of CAD (638–644). In individual trials and meta-analyses, the use of bivalirudin has been associated with reduced bleeding compared with UFH plus a GP IIb/IIIa inhibitor, although concerns about ischemic events have emerged in individual studies (625, 637–645). Longer-term follow-up of the major bivalirudin trials, however, suggests that small or nominal increases in ischemic events have not translated into long-term consequences and that treatment at or before the time of PCI with clopidogrel may mitigate any increased early ischemic risk (637–645). Thus, a treatment strategy of bivalirudin compared with heparin (or enoxaparin) plus GP IIb/IIIa inhibitor appears to lower the risk of bleeding complications. The lower bleeding rates associated with bivalirudin (compared with UFH plus a GP IIb/IIIa inhibitor) are mitigated when used concomitantly with a GP IIb/IIIa inhibitor (639). A strategy of use of provisional GP IIb/IIIa inhibitor in patients treated with bivalirudin is widely accepted (639, 643, 644).

In patients with heparin-induced thrombocytopenia (671, 672), a direct-thrombin inhibitor (argatroban) has been approved as an alternative parenteral anticoagulant to be used during PCI (668). The use of bivalirudin for heparin-induced thrombocytopenia has been reported as well (669).

5.7.4.5. FONDAPARINUX: RECOMMENDATION

CLASS III: HARM

1. Fondaparinux should not be used as the sole anticoagulant to support PCI. An additional anticoagulant with anti-IIa activity should be administered because of the risk of catheter thrombosis (651, 652). *(Level of Evidence: C)*

Fondaparinux, a pentasaccharide, is an indirect factor Xa inhibitor but has no effect on thrombin. On the basis of reports of catheter thrombosis when fondaparinux is used alone during primary PCI (651, 652), the writing committee recommends that an anticoagulant with anti-IIa activity be used in patients undergoing PCI (651, 652). One study suggested that clinical outcomes were better when fondaparinux was replaced during PCI by a standard dose of UFH (85 U/kg, 60 U/kg with GP IIb/IIIa inhibitors) rather than by a low dose (50 U/kg) (673).

5.7.5. No-Reflow Pharmacological Therapies: Recommendation

CLASS IIa

1. Administration of an intracoronary vasodilator (adenosine, calcium channel blocker, or nitroprusside) is reasonable to treat PCI-related no-reflow that occurs during primary or elective PCI (674–689). *(Level of Evidence: B)*

See Online Data Supplement 25 for additional data regarding no-reflow therapies.

No-reflow is a broad term used to describe 2 distinct entities. The first is "interventional no-reflow" attributed to vasospasm and downstream embolization of debris dislodged during PCI, usually in the setting of atherectomy, thrombus, or degenerated SVGs. The second entity is suboptimal reperfusion of an infarct artery, attributed to endothelial injury in addition to embolization and vasospasm. Angiographic no-reflow is the most obvious sequela of the same

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

pathophysiology that produces abnormal TIMI frame counts and TIMI blush scores, so these measures are often used interchangeably. The principal clinical sequela of no-reflow is myonecrosis. Efforts to prevent no-reflow overlap with strategies to reduce MI size and prevent periprocedural MI.

In the setting of MI, several drugs have been shown to reduce the incidence of no-reflow. Evidence for a beneficial effect on no-reflow exists for abciximab, adenosine, nicorandil, and nitroprusside (674, 675, 680, 682, 683, 685, 687, 688, 690). However, their adoption into clinical practice has depended on their effect on hard clinical endpoints such as infarct size and mortality. These benefits, and consequentially the use of these agents, have been limited.

For interventional no-reflow, several therapies have proven effective after no-reflow has started. These include adenosine, calcium channel blockers, and nitroprusside (676, 678, 679, 681, 684, 686, 689, 691). There are fewer data to support the use of epinephrine (692). No-reflow after rotational atherectomy was less common with nicorandil compared with verapamil infusions in 3 studies (693–695), and an infusion of nicorandil/adenosine during rotational atherectomy prevented no-reflow in 98% of patients (677). Trials of pre-PCI intracoronary verapamil, nicardipine, and adenosine have reported them to be safe but have not demonstrated reductions in post-PCI no-reflow (696–698). Mechanical devices to prevent interventional and myocardial infarct reperfusion no-reflow are also covered in Section 5.5.5.

5.8. PCI in Specific Anatomic Situations

5.8.1. CTOs: Recommendation

CLASS IIa

1. PCI of a CTO in patients with appropriate clinical indications and suitable anatomy is reasonable when performed by operators with appropriate expertise (699–703). *(Level of Evidence: B)*

See Online Data Supplements 26 to 28 for additional data regarding CTOs.

Approximately one third of patients with suspected CAD who undergo coronary angiography have $\geq$ 1 CTO (defined as occlusion of a duration >3 months) (704). Although stress-induced ischemia can be elicited in the majority of patients with CTO despite the presence of collaterals (706, 707), only 8% to 15% of these patients undergo PCI (708, 709). The disparity between the frequency of CTOs and percutaneous treatment underscores not only the technical and procedural complexities of this lesion subtype but also the clinical uncertainties regarding which patients benefit from CTO revascularization. Studies suggest that patients who undergo successful, rather than failed, recanalization of CTOs fare better in terms of symptom status and need for CABG (699), as well as LV function (710). However, the impact of successful CTO recanalization on long-term survival remains unsettled (701, 711, 712). The decision to try PCI for a CTO (versus continued medical therapy or surgical revascularization) requires an individualized risk-benefit analysis encompassing clinical, angiographic, and technical considerations. Consultation with a cardiothoracic surgeon and use of the Heart Team approach in cases of CTO in which a large territory is subtended and/or multivessel CAD is present are frequently done.

From a technical perspective, successful recanalization of CTOs has steadily increased over the years because of adoption of dedicated wires, novel techniques, and increased operator experience (702). In patients who undergo successful CTO recanalization, use of DES significantly reduces the need for repeated target-vessel revascularization, compared with BMS and balloon angioplasty, without compromising safety (703, 713–719).

5.8.2. SVGs: Recommendations

CLASS I

1. EPDs should be used during SVG PCI when technically feasible (532–535). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. Platelet GP IIb/IIIa inhibitors are not beneficial as adjunctive therapy during SVG PCI (212, 571, 720, 721). *(Level of Evidence: B)*

CLASS III: HARM

1. PCI is not recommended for chronic SVG occlusions (722–724). *(Level of Evidence: C)*

See Online Data Supplement 29 for additional data regarding SVG.

Adverse cardiac event rates are doubled after SVG PCI compared with native-artery PCI (536). A distal balloon occlusion EPD decreased the 30-day composite outcome of death, MI, emergency CABG, or target-lesion revascularization (9.6% versus 16.5%) in the only RCT comparing embolic protection with no embolic protection (532). Subsequent noninferiority comparisons have demonstrated similar benefit with proximal occlusion and distal filter EPDs, with benefit limited to reduction in periprocedural MI (534, 535). PCI in chronic SVG occlusion is associated with low success rates, high complication rates, and poor long-term patency rates (722, 723). Restenosis and target-vessel revascularization rates are lower with DES compared with BMS, although mortality and stent thrombosis rates are similar (725). The use of covered stents is

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 43

limited to the treatment of the uncommon complication of SVG perforation. Balloon angioplasty for distal SVG anastomotic stenoses has low restenosis rates (724), so stenting is commonly reserved at this location for suboptimal balloon angioplasty results or restenosis. Routine GP IIb/IIIa inhibitor therapy has not proven beneficial in SVG PCI (720). Fibrinolytic therapy is no longer used for thrombus-containing lesions, but rheolytic or manual aspiration thrombectomy is sometimes employed.

5.8.3. Bifurcation Lesions: Recommendations

CLASS I

1. Provisional side-branch stenting should be the initial approach in patients with bifurcation lesions when the side branch is not large and has only mild or moderate focal disease at the ostium (726–729). *(Level of Evidence: A)*

CLASS IIa

1. It is reasonable to use elective double stenting in patients with complex bifurcation morphology involving a large side branch where the risk of side-branch occlusion is high and the likelihood of successful side-branch reaccess is low (730–733). *(Level of Evidence: B)*

Side-branch occlusion or severe stenosis after stenting the main artery in coronary bifurcation PCI occurs in 8% to 80% of unselected patients (732, 734). The frequency of side-branch occlusion is related to complex bifurcation morphology (severe and/or long side-branch ostial stenosis, large plaque burden in the side-branch ostium, and/or unfavorable side-branch angulation) (732, 735, 736). Side-branch occlusion after PCI is associated with Q-wave and non-Q-wave MI (734, 735). Therefore, preservation of physiologic flow in the side branch after PCI is important (736). There are 2 bifurcation PCI strategies: provisional stenting (stenting the main vessel with additional balloon angioplasty or stenting of the side branch only in the case of an unsatisfactory result) and elective double stenting of the main vessel and the side branch. When there is an unsatisfactory result in the side branch from the provisional stent in the main branch, sometimes balloon angioplasty alone in the side branch will improve the result and stenting the side branch is not necessary. Some experts have suggested that using the side-branch balloon alone will distort the main branch stent and thus this always needs to be a kissing balloon inflation.

In patients with low-risk bifurcation lesions (minimal or moderate ostial side-branch disease [<50% diameter stenosis] of focal length [5 to 6 mm]), provisional stenting yields similar clinical outcome to elective double stenting, with lower incidence of periprocedural biomarker elevation (726–729). Conversely, in patients with high-risk bifurcations, elective double stenting is associated with a trend toward higher angiographic success rates, lower in-hospital MACE, and better long-term patency of the side branch compared with provisional stenting (193). Culotte, Crush, and T-stent techniques have been studied in RCTs (726–729, 737). Use of DES yields better outcomes than BMS (738), and sirolimus-eluting stents yield better outcomes than paclitaxel-eluting stents (739–742). Clinical evidence supports the use of final kissing balloon inflation after elective double stenting (743).

5.8.4. Aorto-Ostial Stenoses: Recommendations

CLASS IIa

1. IVUS is reasonable for the assessment of angiographically indeterminant left main CAD (744, 745). *(Level of Evidence: B)*
2. Use of DES is reasonable when PCI is indicated in patients with an aorto-ostial stenosis (746, 747). *(Level of Evidence: B)*

Aorto-ostial stenoses of native coronary arteries (left main coronary artery and right coronary artery) are most commonly caused by atherosclerosis, but they can also occur in patients with congenital malformations, radiation exposure, vasculitides, and aortic valve replacement. The angiographic diagnosis of aorto-ostial disease is not always straightforward, especially in the ostial left main coronary artery, where eccentricity and angulation can be mistaken for stenosis (490, 748). Aorto-ostial disease can be evaluated with IVUS (744, 745); FFR (with IV adenosine) has also been used (484, 749). The treatment of aorto-ostial stenoses with balloon angioplasty has been associated with lower procedural success rates, more frequent in-hospital complications, and a greater likelihood of late restenosis (750). Although atherectomy devices (directional atherectomy, rotational atherectomy, and excimer laser angioplasty) have improved acute angiographic results over balloon angioplasty, restenosis has remained a limitation (751). In patients with aorto-ostial stenoses undergoing PCI, use of DES has been shown to reduce restenosis compared with BMS (176, 746, 752).

5.8.5. Calcified Lesions: Recommendation

CLASS IIa

1. Rotational atherectomy is reasonable for fibrotic or heavily calcified lesions that might not be crossed by a balloon catheter or adequately dilated before stent implantation (514, 515, 520). *(Level of Evidence: C)*

The presence of coronary calcification is a marker for significant CAD and increased long-term mortality

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

(753). Calcified coronary lesions are not a homogenous entity, and their response to PCI varies according to severity of calcification. Severely calcified lesions respond poorly to balloon angioplasty (230, 754), and when stents are implanted in such lesions, an incomplete and asymmetrical stent expansion occurs in the majority of cases (755). Attempts to remedy the underexpanded stents with aggressive high-pressure balloon dilatation may result in coronary artery rupture (756). All the published prospective RCTs that evaluated the various catheter-based coronary interventional devices excluded patients with severely calcified lesions. Therefore, the evidence base for best PCI practices in patients with severely calcified lesions comes from nonrandomized single-arm studies. Among the various adjunct devices that are used to facilitate PCI in severely calcified lesions, only rotational atherectomy has been shown to have potential utility (514, 757). Although rotational atherectomy increases the chances of angiographic success in severely calcified lesions, its use as a stand-alone device has not led to a reduction in restenosis (520, 521, 758). Several retrospective studies have shown that in patients with severely calcified lesions, the use of rotational atherectomy before implantation of BMS (514)or DES(515)is safe. Intermediate-term patency is more favorable with DES than BMS (759).

5.9. PCI in Specific Patient Populations

Several specific patient subsets with higher risks for PCI, and at times higher absolute clinical benefit, have traditionally been underrepresented in RCTs and are described below.

5.9.1. Elderly. The elderly constitute a growing proportion of patients considered for PCI (760). In 1 series examining trends over a 25-year period, the proportion of patients undergoing PCI who were 75 to 84 years of age doubled, and those >85 years of age increased 5-fold (761). Age is one of the strongest predictors of mortality after PCI (762), and elderly patients present with a substantially higher clinical risk profile (760). Nonetheless, the angiographic success rates and clinical benefits of PCI in elderly patients are similar to younger patients (763). In fact, the absolute benefit is typically greater because of higher absolute risk of adverse outcomes in these patients (764). However, increased risks of complications such as major bleeding and stroke mandate careful consideration of the benefits and risks of PCI in elderly patients (373).

5.9.2. Diabetes. Patients with diabetes represent approximately one third of patients undergoing PCI in the United States. Restenosis, which had been a major limitation of PCI, is significantly reduced in patients with diabetes treated with DES compared with BMS (471). However, there are no definitive data from RCTs supporting different clinical outcomes for different types of DES (765), with a recent meta-analysis of 35 RCTs involving 3,852 patients with diabetes unable to find major differences between patients receiving sirolimus-eluting stents or paclitaxel-eluting stents (472). Numerous analyses and clinical studies have evaluated how the presence of diabetes may impact the clinical outcome of patients undergoing PCI and decisions about PCI or CABG (14, 116, 163, 164, 186). These studies and the approach to revascularization decisions in diabetes are addressed in Section 4.

Diabetes is an important risk factor for the development of contrast-induced AKI. Strategies to reduce the risk of contrast-induced AKI in patients with diabetes are discussed in Section 4.4.

5.9.3. Women. Cardiovascular disease is the leading cause of death in women in the United States and Europe (766), and an estimated 35% of PCIs in the United States are performed in women (767, 768). Women undergoing PCI usually have more risk factors (including hypertension, advanced age, elevated cholesterol, and more significant and diffuse CAD) compared with men (769). Women with STEMI are also less likely to receive early medical treatments and experience longer delays to reperfusion therapy (770, 771). In subgroup analyses of clinical trials, use of DES appears to be similarly efficacious in women and men (772).

5.9.4. CKD: Recommendation

CLASS I

1. In patients undergoing PCI, the glomerular filtration rate should be estimated and the dosage of renally cleared medications should be adjusted (298–300). *(Level of Evidence: B)*

CKD is an independent risk factor for the development and progression of CAD (773, 774), and is also associated with worse prognosis after MI or PCI (369, 775). A glomerular filtration rate of <60 mL/min per 1.73 m^2 of body surface area should be considered abnormal. Patients with CKD undergoing PCI have a higher risk ofcomplications, including bleeding (776), AKI, and death (236, 777), but CKD is not a strong predictor of restenosis after BMS or DES (778). Strategies to reduce the risk of contrast-induced AKI in patients with CKD are discussed in Section 4.4. Platelet dysfunction and overdosing of antiplatelet and antithrombin drugs (350) in patients with CKD contribute to the increased risk of bleeding. The Cockcroft-Gault formula is commonly used as a surrogate marker for estimating creatinine clearance, which in turn estimates glomerular filtration rate (298, 299, 779, 780).

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 45

Medications that require dosage adjustments in patients with CKD include eptifibatide, tirofiban, bivalirudin, enoxaparin, and fondaparinux (781).

5.9.5. Cardiac Allografts. Cardiac allograft vasculopathy is a major cause of death in cardiac transplant recipients after their first year of survival (782). In general, revascularization for cardiac allograft vasculopathy with PCI is only palliative, with no evidence supporting benefit in regard to long-term survival or avoidance of retransplantation. The restenosis rate after PCI in patients with cardiac allograft vasculopathy is high, although stent implantation reduces early and midterm reste-nosis compared with balloon angioplasty. DES have been shown to have a tendency to lower restenosis rates compared with BMS (783, 784). Thus, many clinicians perform stenting with DES or BMS in cardiac transplant patients with discrete lesions who have an abnormal stress test or symptoms suggestive of myocardial ischemia.

5.10. Periprocedural MI Assessment: Recommendations

CLASS I

1. In patients who have signs or symptoms suggestive of MI during or after PCI or in asymptomatic patients with significant *persistent* angiographic complications (e.g., large side-branch occlusion, flow-limiting dissection, no-reflow phenomenon, or coronary thrombosis), creatinine kinase-MB and troponin I or T should be measured. *(Level of Evidence: C)*

CLASS IIb

1. Routine measurement of cardiac biomarkers (creatinine kinase-MB and/or troponin I or T) in all patients after PCI may be reasonable. *(Level of Evidence: C)*

Major events leading to ischemia or MI after PCI include acute closure, embolization and no-reflow, side-branch occlusion, and acute stent thrombosis. Issues surrounding the routine assessment of cardiac biomarkers after PCI are complex, especially given that the definition of PCI-related MI has evolved over the years and most events are asymptomatic. The most recent consensus definition of MI considers troponin elevations of 3 times the upper limit of normal as a PCI-related MI in patients with normal baseline levels; this is further classified as a type 4a MI (240). This definition is supported by studies with delayed-enhancement MRI confirming that there is irreversible injury in the myocardium associated with biomarker elevations and that the size of this injury correlates with the degree of elevation (785). Furthermore, a meta-analysis of 15 observational studies found that troponin elevations at any level were linked with worse in-hospital and long-term outcomes; elevations >3 times the upper limit of normal predicted even worse outcomes (242). Other observational data, however, have raised concerns about whether the relationship is causal (786, 787). A recent study found creatinine kinase-MB to correlate better with MRI-detected MI than troponin level (788). Definitions of PCI-related MI are being reevaluated by the Task Force for the Redefinition of Myocardial Infarction. Although there may be value for individual operators and hospitals to routinely measure cardiac biomarkers to track rates of PCI-related MI, at present there are not compelling data to recommend this for all PCI procedures.

5.11. Vascular Closure Devices: Recommendations

CLASS I

1. Patients considered for vascular closure devices should undergo a femoral angiogram to ensure their anatomic suitability for deployment. *(Level of Evidence: C)*

CLASS IIa

1. The use of vascular closure devices is reasonable for the purposes of achieving faster hemostasis and earlier ambulation compared with the use of manual compression (257, 789–791). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. The routine use of vascular closure devices is not recommended for the purpose of decreasing vascular complications, including bleeding (256, 257, 789–792). *(Level of Evidence: B)*

See Online Data Supplement 30 for additional data regarding vascular closure devices.

Vascular (arteriotomy) closure devices have been extensively reviewed (790), most recently in a 2010 AHA scientific statement (257), which issued several formal recommendations. The results of 4 meta-analyses have found that vascular closure devices decrease time to hemostasis compared with manual compression but do not decrease vascular complications, bleeding complications, or the need for blood transfusions (256, 789, 791, 793). Future studies of vascular closure devices need to be randomized, include "high-risk" patients and "high-risk" anatomy, use blinded endpoint adjudication as much as possible, use well-defined and comprehensive complication endpoints, and be adequately powered to

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

detect clinically important endpoints, particularly bleeding and vascular complications.

6. POSTPROCEDURAL CONSIDERATIONS

Postprocedural considerations in patients undergoing PCI are discussed below and summarized in Table 14. Some recommendations and text regarding DAPT in Section 5.7.2 are intentionally repeated in this section for reader ease of use.

T14

6.1. Postprocedural Antiplatelet Therapy: Recommendations

CLASS I

1. After PCI, use of aspirin should be continued indefinitely (560–563). *(Level of Evidence: A)*
2. The duration of $P2Y_{12}$ inhibitor therapy after stent implantation should generally be as follows:
   a. In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ inhibitor therapy should be given for at least 12 months. Options include clopidogrel 75 mg daily (570), prasugrel 10 mg daily (567), and ticagrelor 90 mg twice daily (568). *(Level of Evidence: B)*
   b. In patients receiving DES for a non-ACS indication, clopidogrel 75 mg daily should be given for at least 12 months if the patient is not at high risk of bleeding (208, 212, 571). *(Level of Evidence: B)*
   c. In patients receiving BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks) (572). *(Level of Evidence: B)*
3. Patients should be counseled on the importance of compliance with DAPT and that therapy should not be discontinued before discussion with their cardiologist (208). *(Level of Evidence: C)*

CLASS IIa

1. After PCI, it is reasonable to use aspirin 81 mg per day in preference to higher maintenance doses (302, 573–576). *(Level of Evidence: B)*
2. If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of $P2Y_{12}$ inhibitor therapy after stent implantation, earlier discontinuation (e.g., <12 months) of $P2Y_{12}$ inhibitor therapy is reasonable. *(Level of Evidence: C)*

CLASS IIb

1. Continuation of clopidogrel, prasugrel, or ticagrelor beyond 12 months may be considered in patients undergoing placement of DES (567, 568). *(Level of Evidence: C)*

Continued treatment with the combination of aspirin and a $P2Y_{12}$ inhibitor antagonist after PCI appears to reduce MACE (570, 572). On the basis of RCT protocols, secondary prevention measures, and expert consensus opinion, aspirin 81 mg daily should be given indefinitely after PCI.

Likewise, $P2Y_{12}$ inhibitors should be given for a minimum of1 month after BMS (minimum 2 weeks for patients at significant increased risk of bleeding) (580) and for 12 months after DES and ideally in all patients who are not at high risk of bleeding.

The 2009 STEMI/PCI guidelines update (10) listed the recommendation "if the risk of morbidity because of bleeding outweighs the anticipated benefit afforded by thienopyridine therapy, earlier discontinuation *should be considered*" as a Class I recommendation, although the language used, in part, was consistent with a Class IIa recommendation. To clarify the intent ofthe recommendation, as well as to acknowledge the inherent difficulties in weighing bleeding and stent thrombosis risks, the recommendation is designated a Class IIa recommendation, using the phrase "earlier discontinuation *is reasonable*." Recommendations regarding $P2Y_12$ inhibitor discontinuation before elective or urgent CABG are provided in the "2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft Surgery" (824).

6.1.1. PPIs and Antiplatelet Therapy: Recommendations

CLASS I

1. PPIs should be used in patients with a history of prior gastrointestinal (GI) bleeding who require DAPT (794). *(Level of Evidence: C)*

CLASS IIa

1. Use of PPIs is reasonable in patients with an increased risk of GI bleeding (e.g., advanced age, concomitant use of warfarin, steroids, nonsteroidal anti-inflammatory drugs, *Helicobacter pylori* infection) who require DAPT (794). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Routine use of a PPI is not recommended for patients at low risk of GI bleeding, who have much less potential to benefit from prophylactic therapy (794). *(Level of Evidence: C)*

See Online Data Supplement 31 for additional data regarding the clopidogrel—PPI interaction.

PPIs are often prescribed prophylactically when clopi-dogrel is started to prevent GI complications such

as ulceration and bleeding due to DAPT (825). There is pharmacodynamic evidence that omeprazole interferes with clopidogrel metabolism (826, 827), but there is no clear evidence implicating other PPIs. However, even with omeprazole, there are no convincing data supporting an important clinical drug-drug interaction (826). The FDA communication about an ongoing safety review of clopidogrel advises that healthcare providers avoid the use of clopidogrel in patients with impaired *CYP2C19* function due to known genetic variation or drugs that inhibit *CYP2C19* activity. The FDA notes that there is no evidence that other drugs that reduce stomach acid, such as histamine-2 receptor antagonists (except cimetidine) or antacids, interfere with clopidogrel responsiveness. The COGENT (Clopidogrel and the Optimization of Gastrointestinal Events) trial randomized patients with DAPT to clopidogrel and omeprazole or clopidogrel and placebo, and while there was no difference in cardiovascular events between the 2 groups, GI events were halved in those randomized to omeprazole (828). It is reasonable to carefully evaluate the indication for PPI therapy in patients treated with clopidogrel, based on the presence or absence of the risk factors discussed above (794). The need for GI protection increases with the number of risk factors for bleeding. Prior upper GI bleeding is the strongest and most consistent risk factor for GI bleeding on antiplatelet therapy. Patients with ACS and prior upper GI bleeding are at substantial cardiovascular risk, so DAPT with concomitant use of a PPI may provide the optimal balance of risk and benefit. It should be noted that PPIs, by decreasing adverse GI effects related to clopidogrel, might decrease patients' discontinuation of clopidogrel. In patients in whom there is a clear indication for PPI therapy, some clinicians may choose to use a PPI other than omeprazole.

6.1.2. Clopidogrel Genetic Testing: Recommendations

CLASS IIb

1. Genetic testing might be considered to identify whether a patient at high risk for poor clinical outcomes is predisposed to inadequate platelet inhibition with clopidogrel (829). *(Level of Evidence: C)*
2. When a patient predisposed to inadequate platelet inhibition with clopidogrel is identified by genetic testing, treatment with an alternate $P2Y_{12}$ inhibitor (e.g., prasugrel or ticagrelor) might be considered (829). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. The routine clinical use of genetic testing to screen patients treated with clopidogrel who are undergoing PCI is not recommended (829). *(Level of Evidence: C)*

On March 12, 2010, the FDA approved a new label for clopidogrel with a "boxed warning" about the diminished effectiveness of clopidogrel in patients with impaired ability to convert the drug into its active metabolite (829). Patients with decreased *CYP2C19* function because of genetic polymorphisms metabolize clopidogrel poorly and have higher rates of cardiovascular events after ACS and PCI than patients with normal *CYP2C19* function. The warning also notes that tests are available to identify patients with genetic polymorphisms and that alternative treatment strategies should be considered for patients who are poor metabolizers. The clopidogrel boxed warning leaves the issue of whether to perform *CYP2C19* testing up to the individual physician. It does not specifically require genetic testing or other changes in evaluation or treatment and does not imply that there are solid evidence-based reasons for such actions. Rather, it serves to inform clinicians of genetic variations in response to clopidogrel and to emphasize that clinicians should use this knowledge to make decisions about how to treat individual patients. At the present time, the evidence base is insufficient to recommend routine genetic testing in patients undergoing PCI. There may be a potential role for genetic testing for patients undergoing elective high-risk PCI procedures (e.g., unprotected left main, bifurcating left main, or last patent coronary artery).

6.1.3. Platelet Function Testing: Recommendations

CLASS IIb

1. Platelet function testing may be considered in patients at high risk for poor clinical outcomes (829). *(Level of Evidence: C)*
2. In patients treated with clopidogrel with high platelet reactivity, alternative agents, such as prasugrel or ticagrelor, might be considered (829). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. The routine clinical use of platelet function testing to screen patients treated with clopidogrel who are undergoing PCI is not recommended (829). *(Level of Evidence: C)*

Platelet function testing to tailor antiplatelet therapy has received considerable interest. The GRAVITAS (Gauging Responsiveness With A VerifyNow Assay-Impact On Thrombosis And Safety) trial and several other ongoing trials test the concept that tailoring antiplatelet therapy based on platelet responsiveness assessed in an ex vivo $P2Y_{12}$ assay will improve cardiovascular outcomes (830). In GRAVITAS, treatment with high-dose clopidogrel for 6 months in patients with high platelet reactivity on standard-dose

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

clopidogrel was not beneficial. At the present time, the evidence base is insufficient to recommend routine platelet function testing. The results of 2 ongoing trials (DANTE [Dual Antiplatelet Therapy Tailored on the Extent of Platelet Inhibition] and ARCTIC [Double Randomization of a Monitoring Adjusted Antiplatelet Treatment Versus a Common Antiplatelet Treatment for DES Implantation, and Interruption Versus Continuation of Double Antiplate-let Therapy, One Year After Stenting]) will provide further information on the issue (www.clinicaltrials.gov).

6.2. Stent Thrombosis

The majority of stent thrombosis occurs early (0 to 30 days after PCI). In broad clinical practice, the expected rate of early stent thrombosis is <1%, and beyond 30 days it is 0.2% to 0.6% per year (210, 831). Acute stent thrombosis often presents as STEMI, and emergency revascularization is indicated. Acute stent thrombosis is associated with mortality rates of 20% to 45% (832). Survivors are also at risk of recurrent stent thrombosis (833).

Mechanical and pharmacological factors are the most frequent cause of acute stent thrombosis. After the usual measures to restore flow in the infarct-related artery, it is important to consider the etiology of stent thrombosis as it pertains to further therapy and avoidance of recurrence. IVUS may identify factors such as an undersized stent, incomplete stent apposition, residual stenosis, or dissection and can guide subsequent treatment. The most common cause of acute stent thrombosis is nonadherence to DAPT; however, resistance to aspirin or thienopyridines and pro-thrombotic states such as congenital or acquired thrombophilic states (malignancy) are additional risk factors (834, 835).

Given the poor prognosis of stent thrombosis and the uncertainties surrounding treatment, the importance of prevention must be emphasized. This includes ensuring compliance with DAPT and adequate stent sizing and expansion (836).

6.3. Restenosis: Recommendations

CLASS I

1. Patients who develop clinical restenosis after balloon angioplasty should be treated with BMS or DES if anatomic factors are appropriate and if the patient is able to comply with and tolerate DAPT (837). *(Level of Evidence: B)*
2. Patients who develop clinical restenosis after BMS should be treated with DES if anatomic factors are appropriate and the patient is able to comply with and tolerate DAPT (838–840). *(Level of Evidence: A)*

CLASS IIa

1. IVUS is reasonable to determine the mechanism of stent restenosis (495). *(Level of Evidence: C)*

CLASS IIb

1. Patients who develop clinical restenosis after DES may be considered for repeat PCI with balloon angioplasty, BMS, or DES containing the same drug or an alternative antiproliferative drug if anatomic factors are appropriate and the patient is able to comply with and tolerate DAPT (495). *(Level of Evidence: C)*

6.3.1. Background and Incidence. After balloon angioplasty, mechanisms contributing to restenosis include smooth muscle cell migration and proliferation, platelet deposition, thrombus formation, elastic recoil, and negative arterial remodeling. Stents block elastic recoil and negative remodeling, and the predominant mechanism for restenosis after stent implantation is neointimal hyperplasia. Restenosis rates vary, depending on whether angiographic restenosis (defined as >50% diameter stenosis at follow-up angiography) or clinical restenosis (symptomatic and requiring target-lesion revascularization or target-vessel revascularization) is measured, as well as on patient characteristics, coronary anatomy considerations, and device type (balloon angioplasty, BMS, or DES). The incidence of angiographic restenosis rates for uncomplicated lesions treated in RCTs ranges from 32% to 42% after balloon angioplasty (463, 464) and from 16% to 32% after BMS (463, 464), and is generally <10% after DES (454, 841). Less than half of patients with angiographic restenosis present with symptomatic, clinically relevant restenosis at 1-year follow-up, and a pooled analysis of 6,186 patients from 6 trials of BMS showed target-lesion revascularization was performed in 12% and target-vessel revascularization in 14% at 1 year (842, 843). Patients with clinical restenosis typically present with recurrent exertional angina, but 5% to 10% of patients present with acute MI and 25% with UA (844, 845).

Factors associated with an increased risk of restenosis in various models include clinical setting (STEMI, ACS, daily angina), patient characteristics (diabetes, age <55 to 60 years, prior PCI, male sex, multivessel CAD), lesion location (unprotected left main, SVG), and procedural characteristics (minimum stent diameter ≤2.5 mm, total stent length ≥40 mm) (778, 846).

PCI strategies for treating restenosis after balloon angioplasty, BMS, and DES are reviewed in the following sections. In addition to repeat PCI, intensified medical therapy or CABG are often also reasonable strategies, dependent on initial treatment (e.g., balloon

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

angioplasty, BMS), pattern of restenosis, likelihood of recurrent restenosis, ability to intensify medical therapy, suitability for CABG, and patient preference. Repeat PCI with BMS or DES is not appropriate if the patient is not able to comply with and tolerate DAPT.

6.3.2. Restenosis After Balloon Angioplasty. For clinical restenosis after balloon angioplasty, stent implantation is superior to repeat balloon angioplasty or atheroablation devices. The REST (REstenosis STent) study showed that target-lesion revascularization rates were 10% for stent-treated patients and 27% for balloon-treated patients (p=0.001) (837).

6.3.3. Restenosis After BMS. In-stent restenosis is classified according to these angiographic characteristics: Pattern I includes focal lesions $\leq$10 mm in length; Pattern II is in-stent restenosis >10 mm within the stent; Pattern III includes in-stent restenosis >10 mm extending outside the stent; and Pattern IV is totally occluded in-stent restenosis (847). Treatment of in-stent restenosis with balloon angioplasty, repeat BMS, or atheroablation devices for Patterns I to IV resulted in 1-year target-lesion revascularization rates of 19%, 35%, 50%, and 83%, respectively. For clinical restenosis after BMS, repeat stenting with DES is preferred. Studies have demonstrated lower recurrent restenosis rates with DES compared with BMS or vascular brachytherapy (495, 838–840).

6.3.4. Restenosis After DES. Clinical restenosis after placement of DES is becoming increasingly common due to the large numbers of patients who have been treated with DES. The predominant angiographic pattern for DES in-stent restenosis is focal ($\leq$10 mm in length). Several biologic, mechanical, and technical factors may contribute to DES in-stent restenosis, including drug resistance, hypersensitivity, stent underexpansion, stent strut fracture, nonuniform stent strut coverage, gap in stent coverage, and residual uncovered atherosclerotic lesion. IVUS might be considered to determine the cause for in-stent restenosis and help guide treatment strategy. Interventionists may treat focal DES restenosis with balloon angioplasty and treat nonfocal DES restenosis with BMS, CABG, or repeat DES with the same or an alternative antiproliferative drug (848, 849). Small, observational cohort studies have demonstrated angiographic restenosis rates of 25% to 30% with repeat DES either with the same or an alternative drug (495, 849, 850). There are no RCTs, and the most appropriate treatment of restenosis of DES remains unknown.

6.4. Clinical Follow-Up

At the time of discharge, patients are instructed to contact their physician or seek immediate medical attention if symptoms recur. Most physicians will give the patient instructions on return to work and timing of return to full activities. The importance of strict compliance with aspirin and $P2Y_{12}$ inhibitor therapy is ideally emphasized to the patient at the time of discharge and during follow-up visits.

Secondary prevention measures after PCI are an essential part of long-term therapy, reducing both future morbidity and mortality associated with CAD, and are discussed in Section 6.5. A follow-up visit after PCI is usually scheduled to assess the patient's clinical status, the patient's compliance with secondary prevention therapies, and the success of secondary prevention measures (e.g., blood pressure control, low-density lipoprotein levels, smoking cessation). Routine, periodic stress testing of asymptomatic patients is not considered part of standard patient follow-up.

6.4.1. Exercise Testing: Recommendations

CLASS IIa

1. In patients entering a formal cardiac rehabilitation program after PCI, treadmill exercise testing is reasonable. *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Routine periodic stress testing of asymptomatic patients after PCI without specific clinical indications should not be performed (795). *(Level of Evidence: C)*

Treadmill exercise testing before cardiac rehabilitation provides information about peak exercise capacity and heart rate, helping to stratify patients for the level of supervision during training, and seems reasonable for this purpose (851); nuclear imaging to assess ischemia in this context usually adds little.

The role of exercise testing to evaluate restenosis is much less certain. Although the presence of symptoms may not be a reliable means of detecting restenosis, there is no evidence that the detection of silent restenosis leads to improved outcome (852, 853). Routine testing of all patients after PCI will also lead to many false-positive tests, particularly in the era of DES. As restenosis rates decline from 30% to 10%, the false-positive rate of stress imaging increases from 37% to 77% (854). A recent analysis of a national health insurance claims database and accompanying editorial find that stress testing after PCI is likely overused and rarely leads to repeat revascularization (855, 856). In summary, there is no proven benefit or indication for routine periodic stress testing in patients after PCI, and, thus, it is not indicated (8, 851). In cases in which there is a clear clinical indication for stress testing in a patient after PCI, exercise ECG alone is an insensitive predictor of restenosis (857, 858); therefore, stress

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

imaging is the preferred stress test (8). In cases of recurrent angina after PCI in which the pretest likelihood of restenosis is high and repeat revascularization based on symptoms is likely indicated, most practitioners will proceed directly to cardiac catheterization rather than first obtain stress imaging.

6.4.2. Activity and Return to Work. The timing of return to physical activity depends on the presenting condition as well as previous functional status. For STEMI, for example, daily walking is encouraged immediately, and driving can begin within 1 week after uncomplicated MI if allowed by local motor vehicle laws (859). Sexual activity usually can be resumed within days, provided exercise tolerance is adequate, normally assessed by the ability to climb a flight of stairs (859). Similar recommendations have been issued for UA/NSTEMI (860). Patients with UA who have undergone successful revascularization and are otherwise doing well may return to physical activity on an accelerated schedule, usually within a few days (860).

Return to work is more complex. Return to work rates after MI range from 63% to 94% and are confounded by factors such as job satisfaction, financial stability, and company policies (861). The physical demands and degree of stress of a particular job require that recommendations be individualized. In the PAMI-2 (Primary Angioplasty in Myocardial Infarction) trial, patients were encouraged to return to work 2 weeks after primary PCI for STEMI, and no adverse events were reported (862). In the RITA (Randomized Intervention Treatment of Angina) trial, revascularization with PCI led to earlier return to work compared with CABG, and subsequent employment rates were associated with relief of angina (105). Many practitioners use graded exercise treadmill testing to determine the safety of activity and return to work by measuring the metabolic equivalent of task (MET) level achieved and comparing that level to energy levels required to perform different activities (863).

6.4.3. Cardiac Rehabilitation: Recommendation

CLASS I

1. Medically supervised exercise programs (cardiac rehabilitation) should be recommended to patients after PCI, particularly for moderate- to high-risk patients for whom supervised exercise training is warranted (796–804). *(Level of Evidence: A)*

Participation in cardiac rehabilitation is associated with significant reductions in all-cause mortality (OR: 0.80, 95% CI: 0.68 to 0.93) and cardiac mortality (796, 797). Reports from community-based surveys, which in general enroll older and higher-risk patients than clinical trials, have confirmed that participation in comprehensive rehabilitation is independently associated with a reduction in recurrent MI and reduced mortality (799). Cardiac rehabilitation is also associated with improvements in exercise tolerance, cardiac symptoms, lipid levels, cigarette smoking cessation rates (in conjunction with a smoking cessation program), stress levels, improved medical regimen compliance, and improved psychosocial well-being (800). Cardiac rehabilitation is cost-effective as well (864). Physician referral may be the most powerful predictor of patient participation in a cardiac rehabilitation program (865).

6.5. Secondary Prevention

The treatment of the patient does not end with PCI; secondary prevention measures are a critical component of patient management. Important secondary prevention measures were presented in detail in the "2006 AHA/ACC Guidelines for Secondary Prevention for Patients With Coronary and Other Atherosclerotic Vascular Disease" (562) and have recently been updated in the "AHA/ACCF Secondary Prevention and Risk Reduction Therapy for Patients With Coronary and Other Atherosclerotic Vascular Disease: 2011 Update" (805). The reader is referred to this document for detailed discussions of secondary prevention. Among the important recommendations are the following:

- Lipid management with lifestyle modification *(Class I; Level of Evidence: B)* (805–807) and statin therapy are recommended. *(Level of Evidence: A)* (344, 806, 808–810, 810a) An adequate statin dose should be employed which reduces low-density lipoprotein cholesterol to <100 mg/dL AND achieves at least a 30% lowering of low-density lipoprotein cholesterol. *(Class I; Level of Evidence: C)* (806–810, 810a) It is reasonable to treat patients with statin therapy which lowers low-density lipoprotein cholesterol to <70 mg/dL in very high-risk* patients. *(Class IIa; Level of Evidence: C)* (345,808–810,810a,811,812) Patients who have triglycerides ≥200 mg/dL should be treated with statins to lower non-high-density lipoprotein cholesterol to <130 mg/dL. *(Class I; Level of Evidence: B)* (344, 809, 810, 866) In patients who are very high risk* and have triglycerides ≥200 mg/dL, a non-high-density lipoprotein cholesterol goal of <100 mg/dL is reasonable. *(Class IIa; Level of Evidence: C)* (344, 809, 810, 866).

*Presence of established cardiovascular disease plus 1) multiple major risk factors (especially diabetes), 2) severe and poorly controlled risk factors (especially continued cigarette smoking), 3) multiple risk factors of the metabolic syndrome (especially high triglycerides ≥200 mg/dL plus non-high-density lipoprotein cholesterol ≥130 mg/dL with low high-density lipoprotein cholesterol [40 mg/dL]), and 4) acute coronary syndromes.

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

- Blood pressure control with lifestyle modification *(Class I; Level of Evidence: B)* (813–817) and pharmacotherapy *(Class I; Level of Evidence: A)* (805, 813, 818, 819), with the goal of blood pressure <140/90 mm Hg.
- Diabetes management (e.g., lifestyle modification and pharmacotherapy), coordinated with the patient's primary care physician and/or endocrinologist. *(Class I; Level of Evidence: C)* (805)
- Advising patients on the need for complete smoking cessation. *(Class I; Level of Evidence: A)* (805, 820–823)

7. QUALITY AND PERFORMANCE CONSIDERATIONS

7.1. Quality and Performance: Recommendations

CLASS I

1. Every PCI program should operate a quality-improvement program that routinely 1) reviews quality and outcomes of the entire program; 2) reviews results of individual operators; 3) includes risk adjustment; 4) provides peer review of difficult or complicated cases; and 5) performs random case reviews. *(Level of Evidence: C)*
2. Every PCI program should participate in a regional or national PCI registry for the purpose of benchmarking its outcomes against current national norms. *(Level of Evidence: C)*

PCI quality and performance considerations are defined by attributes related to structure, processes, and risk-adjusted outcomes. Structural attributes include elements such as equipment, supplies, staffing, institutional and operator-level volumes, and the availability of electronic medical records. Processes include strategies for the appropriate patient, protocols for pre- and postprocedural care, appropriate procedural execution and management of complications, and participation in databases and registries for benchmarking performance of the program and individual operator. Risk-adjusted outcomes are the end result of these structures and processes of care, and when available are more reliable measures of quality than the institutional and individual operator volumes discussed in Section 7.4.

PCI process and outcomes assessments can be used for internal quality-improvement efforts and public reporting. Public reporting of institutional risk-adjusted outcomes is becoming more common. Although operator-level outcomes can be assessed and risk adjusted, the results are much less reliable due to lack of statistical power resulting from lower volumes. Any public reporting must use statistical methods that meet the high criteria established by the AHA Work Group (867).

7.2. Training

The cognitive knowledge and technical skill required to perform PCI continue to grow. Details on the training required for interventional cardiology are found in the most recent ACCF Core Cardiology Training Statement (868).

7.3. Certification and Maintenance of Certification: Recommendation

CLASS IIa

1. It is reasonable for all physicians who perform PCI to participate in the American Board of Internal Medicine interventional cardiology board certification and maintenance of certification program. *(Level of Evidence: C)*

The American Board of Internal Medicine established interventional cardiology board certification in 1999 as an "added qualification" to the cardiovascular disease board certification. Since 1990 all certificates from the American Board of Internal Medicine are time limited for a 10-year period and require all diplomats to participate in maintenance of certification to maintain their board-certified status. Maintenance of certification in interventional cardiology requires physicians to document a minimum of 150 interventional cases over the 2 years before expiration of the current certification, complete self-assessment modules of their medical knowledge, participate in practice-based quality-improvement activities, and pass a secure, knowledge-based examination (869–871). For those who cannot meet the case volume requirement, an alternative option is to submit a log of 25 consecutive cases including patient characteristics and procedural outcomes. The maintenance of certification process is likely to change, as the American Board of Internal Medicine intends to evolve maintenance of certification from an episodic event that occurs once every 10 years to a more continuous process of continuous professional development.

7.4. Operator and Institutional Competency and Volume: Recommendations

CLASS I

1. Elective/urgent PCI should be performed by operators with an acceptable annual volume (≥75 procedures) at high-volume centers (>400 procedures) with on-site cardiac surgery (872, 873). *(Level of Evidence: C)*

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

2. Elective/urgent PCI should be performed by operators and institutions whose current risk-adjusted outcomes statistics are comparable to those reported in contemporary national data registries. *(Level of Evidence: C)*
3. Primary PCI for STEMI should be performed by experienced operators who perform more than 75 elective PCI procedures per year and, ideally, at least 11 PCI procedures for STEMI per year. Ideally, these procedures should be performed in institutions that perform more than 400 elective PCIs per year and more than 36 primary PCI procedures for STEMI per year (872, 874–877). *(Level of Evidence: C)*

CLASS IIa

1. It is reasonable that operators with acceptable volume (≥75 PCI procedures per year) perform elective/urgent PCI at low-volume centers (200 to 400 PCI procedures per year) with on-site cardiac surgery (872). *(Level of Evidence: C)*
2. It is reasonable that low-volume operators (<75 PCI procedures per year) perform elective/urgent PCI at high-volume centers (>400 PCI procedures per year) with on-site cardiac surgery. Ideally, operators with an annual procedure volume of fewer than 75 procedures per year should only work at institutions with an activity level of more than 600 procedures per year. Operators who perform fewer than 75 procedures per year should develop a defined mentoring relationship with a highly experienced operator who has an annual procedural volume of at least 150 procedures per year. *(Level of Evidence: C)*

CLASS IIb

1. The benefit of primary PCI for STEMI patients eligible for fibrinolysis when performed by an operator who performs fewer than 75 procedures per year (<11 PCIs for STEMI per year) is not well established. *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. It is not recommended that elective/urgent PCI be performed by low-volume operators (<75 procedures per year) at low-volume centers (200 to 400 procedures per year) with or without on-site cardiac surgery. An institution with a volume of fewer than 200 procedures per year, unless in a region that is underserved because of geography, should carefully consider whether it should continue to offer this service (872). *(Level of Evidence: C)*

Older observational evidence supported a volume-outcome relationship in PCI at both the institutional and operator level (873). However, this relationship is complicated and may be inconsistent across low-volume institutions or operators. More recent data on primary PCI suggest that operator experience may modify the volume-outcome relationship at the institutional level (876, 878). Risk-adjusted outcomes remain preferable to institutional and individual operator volumes as quality measures.

Operator and hospital volume recommendations have been carried over from the 2005 PCI guideline. However, the writing committee recognizes that these volume recommendations are controversial. In addition, after extensive review of all relevant data, the writing committee believes that the LOE in support of all the above recommendations is best categorized as LOE C rather than LOE B as it has been in prior guidelines for some recommendations. We encourage the ACCF/AHA/ACP Clinical Competence and Training writing group for PCI and other expert writing groups to review this issue so that new recommendations can be considered by the next PCI guideline writing committee.

7.5. Participation in ACC NCDR or National Quality Database

Assessment of PCI quality and outcomes is important both at the level of the entire program and at the level of the individual physician. This requires collection of clinical and procedural data for PCI that allows regular comparison of risk-adjusted outcomes and complications with national benchmarks. The ACC NCDR CathPCI Registry is an example of a national registry to fulfill the goals of assessing and benchmarking quality and outcomes.

8. FUTURE CHALLENGES

Although this latest guideline reflects significant advancements in the field of PCI, there remain future challenges to the formulation and updating of guidelines for PCI. The proliferation of studies comparing the many newer drugs and devices with older therapies (or other newer therapies), often using different or novel study endpoints, endpoint definitions, and noninferiority designs, pose increasing challenges to objectively evaluating newer therapies and generating recommendations for their use. Numerous potential advances in the field of PCI, including intracoronary stem cell infusions for chronic and acute ischemic heart disease, designer drugs, novel intracoronary imaging technologies such as optical coherence tomography and virtual histology, new stent composition and designs (e.g., drug-eluting, biodegradable, bifurcation), and drug-eluting balloons were considered for formal evaluation by the current writing committee, but it was thought that

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

there were insufficient data at present to formulate any formal recommendations on these topics. These and other emerging technologies and treatments will need to be addressed in future PCI guidelines.

Finally, with this proliferation of new technology, the amount of data generated in the evaluation of these potential therapeutic advances will grow dramatically, adding significant challenges to future guideline generations. Of note, the Web site www.clinicaltrials.gov currently lists several hundred PCI-related clinical trials.

Henry H. Ting	Mayo Clinic—Professor of Medicine; Assistant Dean for Quality	None	None	None	None	None	None	None

This table represents the relationships of committee members with industry and other entities that were determined to be relevant to this document. These relationships were reviewed and updated in conjunction with all meetings and/or conference calls of the writing committee during the document development process. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$10,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person's gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted.

According to the ACCF/AHA, a person has a *relevant* relationship IF: a) The *relationship or interest* relates to the same or similar subject matter, intellectual property or asset, topic, or issue addressed in the *document*; or b)The *company/entity* (with whom the relationship exists) makes a drug, drug class, or device addressed in the *document*, or makes a competing drug or device addressed in the *document*; or c)The *person or a member of the person's household* has a reasonable potential for financial, professional, or other personal gain or loss as a result of the issues/content addressed in the *document*.

*Writing committee members are required to recuse themselves from voting on sections to which their specific relationships with industry and other entities may apply.

†Significant relationship.

This table represents the relationships of reviewers with industry and other entities that were disclosed at the time of peer review and determined to be relevant. It does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$10,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person's gross income for the previous year. A relationship is considered to be modest if it is less than significant under the preceding definition. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Names are listed in alphabetical order within each category of review.

According to the ACCF/AHA, a person has a *relevant* relationship IF: a) The *relationship or interest* relates to the same or similar subject matter, intellectual property or asset, topic, or issue addressed in the *document*; or b) The *company/entity* (with whom the relationship exists) makes a drug, drug class, or device addressed in the *document*, or makes a competing drug or device addressed in the *document*; or c) The *person or a member of the person's household* has a reasonable potential for financial, professional, or other personal gain or loss as a result of the issues/content addressed in the *document*.

*Significant relationship.

†No financial benefit.

APPENDIX 3. ABBREVIATION LIST

ACS = acute coronary syndromes
AKI = acute kidney injury
BMS = bare-metal stent(s)
CABG = coronary artery bypass graft surgery
CAD = coronary artery disease
CKD = chronic kidney disease
CTO = chronic total occlusion
DAPT = dual antiplatelet therapy
DES = drug-eluting stent(s)
ECG = electrocardiogram
EF = ejection fraction
EPD = embolic protection device
FDA = U.S. Food and Drug Administration
FFR = fractional flow reserve
GDMT = guideline-directed medical therapy
GI = gastrointestinal
GP = glycoprotein
IABP = intra-aortic balloon pump
IV = intravenous
IVUS = intravascular ultrasound
LAD = left anterior descending
LIMA = left internal mammary artery
LV = left ventricular
LVEF = left ventricular ejection fraction
MACE = major adverse cardiac event
MI = myocardial infarction
MRI = magnetic resonance imaging
NCDR = National Cardiovascular Data Registry
PCI = percutaneous coronary intervention
PPI = proton pump inhibitor
RCT = randomized controlled trial
SIHD = stable ischemic heart disease
STEMI = ST-elevation myocardial infarction
SVG = saphenous vein graft
TIMI = Thrombolysis In Myocardial Infarction
TMR = transmyocardial laser revascularization
UA/NSTEMI = unstable angina/non-ST-elevation myocardial infarction
UFH = unfractionated heparin

APPENDIX 4. ADDITIONAL TABLES/FIGURES

APPENDIX 4A. The NCDR CathPCI Risk Score System

Variable	Scoring Response Categories				Risk Score Calculation	
					Total Points	Risk of In-Patient Mortality (%)
Age	<60	≥60, <70	≥70, <80	≥80	0	0.0
	0	4	8	14	5	0.1
Cardiogenic shock	No	Yes			10	0.1
	0	25			15	0.2
Prior CHF	No	Yes			20	0.3
	0	5			25	0.6
Peripheral vascular disease	No	Yes			30	1.1
	0	5			35	2.0
Chronic lung disease	No	Yes			40	3.6
	0	4			45	6.3
GFR	<30	30-60	60-90	>90	50	10.9
	18	10	6	0	55	18.3
NYHA functional class IV	No	Yes			60	29.0
	0	4			65	42.7
PCI status (STEMI)	Elective	Urgent	Emergent	Salvage	70	57.6
	12	15	20	38	75	71.2
PCI status (no STEMI)	Elective	Urgent	Emergent	Salvage	80	81.0
	0	8	20	42	85	89.2
					90	93.8
					95	96.5
					100	98.0

CathPCI indicates catheterization percutaneous coronary intervention; CHF, congestive heart failure; GFR, glomerular filtration rate; NCDR, National Cardiovascular Data Registry; NYHA, New York Heart Association; and STEMI, ST-elevation myocardial infarction. APPENDIX 4B. The SCAI Lesion Classification System

Type I lesions (highest success expected, lowest risk)
1. Does not meet criteria for C lesion
2. Patent

Type II lesions
1. Meets any of these criteria for ACC/AHA C lesion
   - Diffuse (>2 cm length)
   - Excessive tortuosity of proximal segment
   - Extremely angulated segments, >90°
   - Inability to protect major side branches
   - Degenerated vein grafts with friable lesions
2. Patent

Type III lesions
1. Does not meet criteria for C lesion
2. Occluded

Type IV lesions
1. Meets any of these criteria for ACC/AHA C lesion
   - Diffuse (>2 cm length)
   - Excessive tortuosity of proximal segment
   - Extremely angulated segments, >90°
   - Inability to protect major side branches
   - Degenerated vein grafts with friable lesions
   - Occluded for >3 mo
2. Occluded

ACC indicates American College of Cardiology; AHA, American Heart Association; and SCAI, Society for Cardiovascular Angiography and Interventions. Reprinted with permission from Krone et al. (879).

APPENDIX 4C. Strategies to Reduce Radiation Exposure to Patient and Operator

Precautions to minimize exposure to patient and operator
- Use radiation only when imaging is necessary to support clinical care
- Minimize use of cine
- Minimize use of steep angles of x-ray beam
- Minimize use of magnification modes
- Minimize frame rate of fluoroscopy and cine
- Keep the image receptor close to the patient
- Utilize collimation to the fullest extent possible
- Monitor radiation dose in real time to assess patient risk-benefit during procedure

Precautions to specifically minimize exposure to operator
- Use and maintain appropriate protective garments
- Maximize distance of operator from x-ray source and patient
- Keep above-table and below-table shields in optimal position at all times
- Keep all body parts out of field of view at all times

Precautions to specifically minimize exposure to patient
- Keep table height as high as comfortably possible for operator
- Vary imaging beam angle to minimize exposure to any single skin area
- Keep patient's extremities out of beam

APPENDIX 4D. Patient Care Consideration Based on Procedural Radiation Dose

$K_{a,r}$*	P_{KA}†	FT‡	Action
>5 Gray	>500 Gray cm^2	>60 min	Physician charts documentation about why exposure at this level occurred, documents whether multiple skin entry angles were used, assesses risk, educates patient about potential for skin injury, and arranges for appropriate follow-up within 30 d. Phone calls may be sufficient with an office visit arranged if issues/questions arise or a potential tissue injury is suspected.
≥10 Gray			Physician contacts radiation safety officer/medical physicist. The radiation safety officer/medical physicist should perform a detailed analysis of PSD. Document a) FOV, b) skin entrance port number, c) known geometry, with a "rough" geometric setup required. Educate patient about the potential for skin injury and document this in chart. Schedule an office visit in 2 to 4 wk.
PSD§ >15 Gray			If calculated PSD is indeed >15 Gray, the physician and/or radiation safety officer/medical physicist should contact hospital risk management within 24 h. Report the event to the Joint Commission and as needed to the appropriate State Department of Health.

*$K_{a,r}$ is total air kerma at reference point
†P_{KA} is air kerma-area product
‡FT is total fluoroscopy time, does not include cine
§PSD is peak skin dose, which requires calculations made by a qualified physicist.
FOV indicates field of view; and FT, fluoroscopy time.
Adapted with permission from Chambers et al. (317).

APPENDIX 4E. General Considerations in Deciding Between Early Invasive Strategy and Initial Conservative Strategy

Early Invasive Strategy Generally Preferred	Initial Conservative Strategy Generally Preferred or Reasonable
• Recurrent angina or ischemia at rest or with low-level activities despite intensive medical therapy	• Low-risk score (e.g., GRACE, TIMI)
• Elevated cardiac biomarkers (TnT or TnI)	• Absence of high-risk features
• New or presumably new ST-segment depression	• High risk for catheterization-related complications
• Signs or symptoms of heart failure	• Patient not a candidate for revascularization (with either PCI or CABG)
• Hemodynamic instability	• Patient prefers conservative therapy
• High-risk score (e.g., GRACE, TIMI)	
• Sustained ventricular tachycardia	
• PCI within 6 mo	
• Prior CABG	
• Diabetes mellitus	
• Mild to moderate renal dysfunction	
• Reduced LV function (LVEF <40%)	

CABG indicates coronary artery bypass graft surgery; GRACE, Global Registry of Acute Coronary Events; LV, left ventricular; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; TIMI, Thrombolysis In Myocardial Infarction; TnI, troponin I; and TnT, troponin T.

APPENDIX 4F. Agents for Procedural Sedation and Analgesia

Drug	Clinical Effects	Dose	Onset	Duration	Comments
Midazolam	Sedation, anxiolysis. No analgesia.	Initial 0.5 to 1 mg IV, then titrated.	2 to 3 min	45 to 60 min	Reduce dose when used in combination with opioids. May produce paradoxical excitement. Reversible with flumazenil.
Fentanyl	Analgesia	50 mcg IV. May repeat every 3 min, titrate to effect.	3 to 5 min	30 to 60 min	Reduce dosing when combined with benzodiazepines. Reversible with naloxone.
Etomidate	Sedation, anxiolysis. No analgesia.	Sedation: 0.1 mg/kg IV; repeat if inadequate response.	<1 min	5 to 15 min	Respiratory depression may occur; institutional guidelines vary about administration to nonintubated patients by nonanesthesiologists. May cause myoclonus, nausea, and vomiting. Adrenocortical suppression occurs but is rarely of clinical significance. Not reversible.
Propofol	Sedation, anxiolysis. No analgesia.	Load 1 mg/kg IV; may administer additional 0.5 mg/ kg doses as needed to enhance or prolong sedation.	<1 min	5 to 15 min	Frequent hypotension and respiratory depression; institutional guidelines vary concerning administration to nonintubated patients by nonanesthesiologists. Avoid with egg or soy allergies. Not reversible.
Reversal Agents					
Naloxone	Opioid reversal	0.4 to 2 mg IV	2 min	20 to 40 min	If shorter acting than reversed drug, serial doses may be required.
Flumazenil	Benzodiazepine reversal	0.2 mg IV. May repeat every 1 min up to 1 mg.	1 to 2 min	30 to 60 min	If shorter acting than reversed drug, serial doses may be required. Do not use in patients receiving long-term benzodiazepines, cyclosporine, isoniazid, lithium, propoxyphene, theophylline, or tricyclic antidepressants.

IV indicates intravenous.

PREAMBLE

The Society for Cardiovascular Angiography and Interventions (SCAI) coauthored and cosponsored with the American College of Cardiology (ACC) and the American Heart Association (AHA) the percutaneous coronary intervention (PCI) guidelines update, released in November 2005 [1]. This guideline update continued to designate elective PCI without on-site surgery as a Class III indication, and primary PCI for ST-segment elevation myocardial infarction (STEMI) as a class IIb indication in the absence of on-site surgery. The performance of PCI without on-site surgical backup is currently the subject of debate. Although providing the highest quality of care and best outcomes to patients should always be the primary goal, debate on this topic has the potential to supersede quality of patient care issues. Within this context, SCAI developed this Expert Consensus document to determine the current status of PCI without on-site surgery not only in the United States, but globally, and make recommendations regarding the performance of PCI in this circumstance. The focus of this document is to provide a structure that provides the highest quality care to patients undergoing PCI in any circumstance.

WILEY InterScience® DISCOVER SOMETHING GREAT

BACKGROUND

Over the past 20 years, the use and indications for PCI have greatly expanded. It is now well-recognized that PCI is safer and the need for urgent coronary artery bypass graft (CABG) surgery greatly reduced [2]. Primary PCI, when available, has eclipsed fibrinolytic therapy for reperfusion in the treatment of STEMI [3], but is adversely affected by time delays in initiating the PCI procedure [4]. Studies examining patient transport to PCI hospitals have shown suboptimal initial door-to-balloon times, especially in the United States [5]. Efforts to provide primary PCI services locally at community hospitals without on-site cardiac surgery have developed and demonstrate outcomes comparable to facilities that have on-site cardiac surgery [6]. Because it is difficult to sustain a PCI program solely on STEMI patients, elective PCIs are also being performed at facilities without on-site surgery [7], enhancing the debate regarding PCI without on-site surgery.

PREVALENCE AND TRENDS OF PCI WITHOUT ON-SITE SURGERY

Data on the prevalence of PCI performed without on-site surgical backup in the United States are not easily found and are changing rapidly. Data gathered from several sources and believed accurate as of July 2006 indicate primary PCI programs without on-site surgical backup exist in all but 10 states (Alaska, Arkansas, Delaware, Georgia, Mississippi, North Dakota, Rhode Island, South Dakota, Vermont, and Wyoming) plus the District of Columbia. Facilities performing both primary and elective PCI without on-site surgery currently exist in 28 states. A large (n = 18,000) randomized trial of elective PCI without on-site surgery (The Atlantic Cardiovascular Patient Outcomes Research Team Elective Angioplasty Study) is currently enrolling patients and includes facilities in several states where elective PCI without on-site backup has been prohibited.

The exact number of patients receiving PCI at facilities without on-site surgery is unknown. Data from facilities reporting to the CathPCI Registry™ of the ACC-National Cardiovascular Data Registry (ACC-NCDR®) show an increase in the number of both primary and elective PCIs performed without on-site surgical backup [8]. In 2005, 75 of the 463 facilities reporting to the ACC-NCDR were performing PCI without on-site surgical backup.

PCI without on-site surgical backup is being performed in 35 of 39 (90%) countries responding to requests for information and appears to be increasing. For example, 7% of PCI procedures performed in the United Kingdom in 1996 were at facilities without on-site cardiac surgery. By 2004, this increased to 15% with 26% of the PCI centers in the United Kingdom operating without on-site cardiac surgery.

EXISTING GUIDELINES AND COMPETENCY DOCUMENTS

ACC/AHA/SCAI Guidelines

In the 2005 update of this guideline, primary PCI without on-site surgical backup remained a Class IIb indication, and elective PCI without on-site surgery remained a Class III indication. Many other programmatic recommendations were made [1].

European Society of Cardiology Guidelines

In contrast to the ACC/AHA/SCAI guidelines, the 2005 European Society of Cardiology (ESC) guidelines do not comment on PCI without on-site cardiac surgery or issues related to institutional or operator competency [9].

British Cardiac Society and British Cardiovascular Intervention Society Guidelines

The British Cardiac Society and British Cardiovascular Intervention Society (BCIS) guideline, published in 2005, acknowledges and approves PCI without on-site surgical backup and emphasizes a common standard applied across facilities with and without on-site surgical backup so as to avoid two levels of service provision [10].

German Guidelines

The only German guidelines found were published in 1987 [11] and thus may not be relevant today. However, there is substantial evidence that PCI without on-site surgical backup is widely performed in Germany.

The Cardiac Society of Australia and New Zealand Guidelines

Policy statements on support facilities and on the performance of coronary angiography and PCI at rural sites in Australia and New Zealand were published (online) in 2003 and 2005, respectively [12,13]. The Cardiac Society of Australia and New Zealand (CSANZ) guidelines state that PCI is preferably performed in hospitals with on-site surgical support, but acknowledge that the requirements for on-site cardiac surgical facilities may be omitted in certain circumstances, and that appropriately trained individuals can perform coronary interventional procedures safely in hospitals without on-site surgical

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

backup. Furthermore, these documents acknowledge that rural patients have reduced access to diagnostic angiography and interventional procedures and further state that providing these services as close to the patient's place of residence as possible facilitates equity of access, which should result in improved quality of care.

Spanish Society of Cardiology Guidelines

Published in 1999 [14], these guidelines are specific for PCI at hospitals without on-site cardiac surgery. PCI performance without on-site cardiac surgery is not prohibited, provided a program meets certain requirements.

Sociedade Brasileira de Hemodinâmica e Cardiologia Intervencionista

Guidelines from the Brazilian Society of Cardiac Hemodynamics and Intervention (Sociedade Brasileira de Hemodinâmica e Cardiologia Intervencionista) [15] were published in 2003. They use a scheme similar to the ACC/AHA/SCAI guidelines [1] and classify elective PCI without on-site surgical backup as Class III. Primary PCI for STEMI in the absence of on-site surgery is a Class IIa indication; their guidelines do not have a IIb category.

Belgian Working Group on Invasive Cardiology Guidelines

Published in 2003, these guidelines acknowledge the increasing safety and diminishing risk of PCI but conclude that "the current standard practice for elective PCI remains the presence of on-site surgical standby" [16].

PEER-REVIEWED LITERATURE OF PCI WITHOUT ON-SITE SURGERY

There are over 30 published papers or abstracts reporting PCI results without on-site surgical backup. All published data for both primary and elective PCI were derived from retrospective reviews or registries, and thus are subject to unintentional bias and other methodological concerns. These are summarized and referenced in the on-line version of this document. These studies span a time period from 1990 to 2006, and thus incorporate changing treatment paradigms, including fibrinolytic therapy before PCI, glycoprotein IIb/IIIa inhibitors, and coronary artery stents. The total patient number within some of these reports is not easily derived because the studies listed are expanding experiences within the same registry; thus, simple aggregation of outcome data is not appropriate or meaningful. The more recent reports show that both primary and elective PCI without on-site surgical backup are performed with a high success rate, low in-hospital mortality rate, and a low rate of urgent cardiac surgery.

BEST PRACTICES FOR PCI WITHOUT ON-SITE SURGERY

Although no randomized or controlled studies exist and despite the current ACC/AHA/SCAI guideline recommendation, PCI without on-site surgery is being performed in many states and is accepted in many countries throughout the world. Moreover, data from many countries, including the United States, indicate that the use of PCI without on-site surgery is growing [8]. The purpose of this document is neither to challenge the ACC/AHA/SCAI guideline recommendations nor to support PCI without on-site surgery backup. However, with the reality that PCI without on-site surgery is growing, it is both appropriate and necessary to define the best standards of practice such that facilities and physicians operate within the highest possible quality standards.

Qualifications of the Physician

Simply performing a high volume of cases does not guarantee technical expertise or sound judgment on the part of the physician. More important than a specific case volume threshold is the accurate assessment of complication rates and patient outcomes. Recommendations for physicians performing PCI at facilities without on-site surgery include the following:

a. Only operators with complication rates and outcomes equivalent or superior to national benchmarks should perform PCI procedures with or without on-site surgery. The operator also must actively participate in a facility's quality improvement program. In addition to involvement in local continuous quality improvement efforts, participation in a national data registry if available and appropriate continuing medical education is mandatory.
b. A proven record of satisfactory outcomes is of greater importance than simply meeting an arbitrary case volume requirement. However, operators must have sufficient prior experience to allow assessment of their judgment and quality. The initial operators at a facility without on-site backup should not begin performing PCI in such facilities until they have a lifetime experience of >500 PCIs as primary operator after completing fellowship. Interventional cardiologists joining those already engaged in PCI without on-site surgery with <500 cases of lifetime experience should be mentored and monitored by existing physicians until it is determined and certi-

TABLE I. Personnel and Facility Requirements for PCI Programs Without On-Site Surgical Backup

Experienced nursing and technical laboratory staff with training in interventional laboratories. Personnel must be comfortable treating acutely ill patients with hemodynamic and electrical instability.
On-call schedule with operation of laboratory 24 hr/day, 365 days/year[a].
Experienced coronary care unit nursing staff, comfortable with invasive hemodynamic monitoring, temporary pacemaker operation, and intraaortic balloon pump management. Personnel capable of endotracheal intubation and ventilator management both on-site and during transfer if necessary.
Full support from hospital administration in fulfilling the necessary institutional requirements, including appropriate support services (e.g., respiratory care, blood bank, etc.).
Written agreements for the emergency transfer of patients to a facility with cardiac surgery. Transport protocols should be developed and tested a minimum of twice per year.
Well-equipped and maintained cardiac catheterization laboratory with high-resolution digital imaging capability and intraaortic balloon pump equipment compatible with transport vehicles. The ability for the real-time transfer of images and hemodynamic data (via T-1 transmission line) as well as audio and video images to review terminals for consultation at the facility providing surgical backup support is ideal.
Appropriate inventory of interventional equipment, including guide catheters, balloons, and stents in multiple sizes, thrombectomy and distal protection devices, covered stents, temporary pacemakers, pericardiocentesis trays. Pressure wire device and intravascular ultrasound equipment are optimal but not mandatory. Rotational or other atherectomy devices should be used cautiously in these facilities due to the greater risk of perforation.
Meticulous clinical and angiographic selection criteria for PCI (Tables II and III).
Performance of primary PCI as the treatment of first choice for STEMI to ensure streamlined care paths and increased case volumes. Door-to-balloon times should be tracked and be $\leq$90 min. Outlier cases should be carefully reviewed for process improvement opportunities.
On-site rigorous data collection, outcomes analysis, benchmarking, quality improvement, and formalized periodic case review.
Participation in a national data registry where available, such as the American College of Cardiology-National Cardiovascular Data Registry® in the United States.

CABG, coronary artery bypass graft; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation acute myocardial infarction.
[a]Required for the United States facilities, but this may not be possible for all facilities world-wide.
Adapted from Ref. 6.

TABLE II. Recommendations for Primary PCI and Emergency Aortocoronary Bypass Surgery at Hospitals Without On-Site Cardiac Surgery

Avoid intervention in:
Patients with >50% stenosis of left main artery proximal to infarct-related lesion especially if the area in jeopardy is relatively small and the overall LV function is not severely impaired.
Long, calcified or severely angulated target lesions at high-risk for PCI failure with TIMI grade 3 flow present during initial diagnostic angiography.
Lesions in other than the infarct artery (unless they appeared to be flow-limiting in patients with hemodynamic instability or ongoing symptoms).
Lesions with TIMI grade 3 flow that are not amenable to stenting in patients with left main or three-vessel disease that will require coronary bypass surgery.
Culprit lesions in more distal branches jeopardizing only a modest amount of myocardium when there is more proximal disease that could be worsened by attempted intervention.
Transfer emergently for coronary bypass surgery patients with:
High-grade left main or three-vessel coronary disease with clinical or hemodynamic instability after successful or unsuccessful PCI of an occluded vessel and preferably with intra-aortic balloon pump support.
Failed or unstable PCI result and ongoing ischemia, with intra-aortic balloon pump support during transfer.

LV, left ventricular; PCI, percutaneous coronary intervention; TIMI, Thrombolysis in Myocardial Infarction.
Adapted from Ref. 6.

fied formally by that hospital that their skills and judgment are excellent and outcomes equivalent or superior to the national benchmarks.

c. Operators performing PCI without on-site surgery should perform $\geq$100 total PCIs per year, including $\geq$18 primary PCIs per year. These numbers exceed those currently recommended in the ACC/AHA/SCAI guidelines to reflect the opinion of this writing group that a greater experience level is appropriate for PCI in this setting.
d. In the United States, board certification in interventional cardiology by the American Board of Internal Medicine is strongly recommended for all physicians performing PCI.

Facilities and Support Personnel

It is essential that all support personnel have adequate education regarding the management of PCI patients before, during, and after the procedure. This knowledge should include potential procedural complications and their management and the drug therapies used in PCI patients (Table I).

Facilities performing both primary and elective procedures without on-site surgery should perform a minimum of 200 PCI/year. Programs with <200 PCI/year should be reviewed on an individual basis. They should remain open only if they are in geographically isolated or under-served areas and their performance metrics are equivalent to accepted benchmarks. We recommend that each country or state review this issue, and establish an absolute minimum annual case volume below which a PCI program must close under any circumstance. In the United States, this minimum should be 150 PCI/year for a program offering both primary and elective PCIs and this must include a minimum of 36 primary PCI/year. Programs offering only primary PCIs must perform a minimum of 36 primary PCIs/year to remain operational. At the present time in the United States, there is no justification for a PCI

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

TABLE III. Recommendations for Patient and Lesion Selection and Backup Strategy for Nonemergent PCI at Hospitals Without On-site Cardiac Surgery and by Operators Performing ≥100 PCIs/Year

Patient Risk: expected clinical risk in case of occlusion caused by procedure.

High Patient Risk: Patients with any of the following:

- decompensated congestive heart failure (Killip Class 3) without evidence for active ischemia, recent CVA, advanced malignancy, known clotting disorders;
- left ventricular ejection fraction ≤25%;
- left main stenosis (≥50%) or three-vessel disease unprotected by prior bypass surgery (>70% stenoses in the proximal segment of all major epicardial coronary arteries);
- single target lesion that jeopardizes over 50% of remaining viable myocardium.

Lesion Risk: probability that procedure will cause acute vessel occlusion.

Increased Lesion Risk: lesions in open vessels with any of the following characteristics:

- diffuse disease (>2 cm in length) and excessive tortuosity of proximal segments;
- more than moderate calcification of a stenosis or proximal segment;
- location in an extremely angulated segment (>90°);
- inability to protect major side branches;
- degenerated older vein grafts with friable lesions;
- substantial thrombus in the vessel or at the lesion site;
- any other feature that may, in the operator's judgment, impede successful stent deployment.
- aggressive measures to open chronic total occlusions are also discouraged due to an increased risk of perforation.

Strategy for Surgical Backup Based on Lesion and Patient Risk:

High-Risk Patient with High-Risk Lesion should not undergo nonemergent PCI at a facility without on-site surgery.

High-Risk Patient with Not High-Risk Lesion: nonemergent patients with this profile may undergo PCI, but confirmation that a cardiac surgeon and operating room is immediately available is necessary.

Not High-Risk Patient with High-Risk Lesion requires no additional precautions.

Not High-Risk Patient with Not High-Risk Lesion requires no additional precautions. Best scenario for PCI without on-site surgery.

CVA, cerebrovascular accident; PCI, percutaneous coronary intervention. Adapted from Ref. 6.

TABLE IV. Requirements for Off-Site Surgical Backup

1. Interventional cardiologists establish a working relationship with cardiac surgeons at the receiving facility.
2. Cardiac surgeon must have privileges at the referring facility to allow review of treatment options as time allows.
3. Cardiac surgeons and receiving hospital agree to provide cardiac surgical backup for urgent cases at all hours and for elective cases at mutually agreed hours
4. Surgeon and receiving facility assure that patient will be accepted based on medical condition, capacity of surgeons to provide services at the time of request and availability of resources. If this cannot be assured before starting an elective procedure, the case should not be done at that time.
5. Interventional cardiologist must review with the surgeon the immediate needs and status of any patient transferred for urgent surgery.
6. Hospital administrations from both facilities endorse transfer agreement.
7. Transferring and receiving facility establish a rigorous protocol for the rapid transfer of patients, including the proper personnel with appropriate experience.
8. Transport provider is available to begin transport within 20 min of the request and provide vehicle/helicopter with necessary life-sustaining equipment, including IABP and monitoring capability.
9. Transferring physician obtains consent for surgery from patient or appropriate surrogate.
10. Initial informed consent for PCI discloses that procedure is being done without on-site surgical backup and acknowledges possibility of risks related to transfer. The consent process should include the risk of urgent surgery (~0.3%) and state that a written plan for transfer exists.
11. As part of the local continuous quality improvement program, a regular review of all patients transferred for emergency surgery with the outcome of surgery and identification of any improvement opportunities.

IABP, intraaortic balloon pump; PCI, percutaneous coronary intervention.

program without on-site surgery to perform only elective procedures or not provide availability to primary PCI 24 hr/day, but such a situation may exist in other countries and be appropriate. New programs should have 2 years to reach the absolute minimum volume, but after that programs failing to reach this volume for 2 consecutive years should not remain open under any circumstance.

Patient and Lesion Selection

Rigorous clinical and angiographic selection criteria are essential for programs performing PCI without on-site surgery. Since the clinical situation and risk-to-benefit ratio are different for primary versus elective PCI, different criteria and standards should apply (Table II). In elective PCI without on-site surgery, it is necessary to assess not only the likelihood of PCI failure, but also the potential patient risk if complications occur since it is possible to have a low-risk lesion in a high-risk patient and vice versa. It is important to consider both the patient and lesion risk when developing criteria for selection of appropriate patients for treatment in facilities without on-site surgery (Table III).

Requirements for Off-Site Surgery

A close alliance and cross-communication with cardiovascular surgeons with formalized agreements and periodically tested protocols for the emergency transfer of patients are essential (Table IV). Interventional cardiologists and cardiac surgeons must be actively involved in the program with attendance at regularly scheduled cardiac catheterization conferences and participation in risk management activities.

In hospitals with on-site surgery, it is no longer standard for a surgical suite to be held open awaiting the completion of a PCI. Because the need for urgent

surgery is so infrequent, there are no current data regarding the actual time required to transport a patient to the operating room and initiate cardiopulmonary bypass should the need arise. Should a patient undergoing PCI at a facility without on-site surgery develop a complication requiring urgent transfer for surgery, it is unclear whether or by how much the facility-to-facility transport would add an additional delay in the current practice environment where operating rooms are not held open at on-site facilities. Minimizing the time to the initiation of cardiopulmonary bypass is the goal in this situation and more likely is feasible with on-site cardiac surgery if that surgery is immediately available. There is no acknowledged goal with supporting data similar to a door-to-balloon time for the initiation of cardiopulmonary bypass in this situation, but this should always be accomplished as rapidly as possible, with the goal of <120 min. Operators at facilities without on-site surgical backup should activate the emergency transport system at the first clear signs of a complication even if they attempt to salvage the situation using percutaneous techniques.

Monitoring of Programs

Providing the highest quality PCI services to patients mandates the collection of outcome data and comparison of these data to established benchmarks. Regardless of the mechanism, all PCI programs, with or without on-site surgical backup, must collect appropriate outcome data and compare their data to state, national or their country's performance standards. Data submitted must be audited by an independent authority periodically to insure integrity of the entire process.

UNRESOLVED ISSUES AND FUTURE DIRECTIONS

PCI without on-site surgery is a polarizing and emotional issue for many individuals both within and external to the interventional community. Although debate has focused on whether facilities that offer PCI without on-site surgery should exist, a more meaningful approach would focus on the goal of providing the best possible care to patients who require PCI, regardless of the setting. Recent publications suggest this goal is not being consistently met. Data indicate that the number of coronary artery bypass operations is declining. This trend is likely to continue, resulting in the closing of smaller surgical programs and the coalescence of cardiac surgical services to more centralized locations. If cardiac surgery programs begin to shrink, it will become more difficult for all PCI facilities to have on-site cardiac surgery.

It is inappropriate to open PCI centers if they are not based on the health needs of the community. Opening a low-volume PCI program within the same geographic area and thereby converting a high-volume program at another facility to a low-volume program is not necessarily in the best interests of patients in the community. There is clearly a potential for unnecessary or inappropriate PCI program development in the same geographic area and this is strongly discouraged. However, the factors that define a geographic area are not consistent throughout the United States or other countries. The level and availability of emergency transport services, response times of emergency medical transport, immediate availability of qualified cath lab personnel, and coverage by interventional cardiologists must be considered.

Desires for personal or institutional financial gain, prestige, market share, or other similar motives should not be part of the decision process in determining the need for a PCI program. These considerations apply equally to those wishing to start a new PCI program without on-site backup and those wishing to protect existing programs with on-site backup. In the final analysis, every PCI procedure, regardless of where it is performed, should be of the highest possible quality. This means the PCI is done for appropriate clinical indications, by a skilled operator with documented satisfactory outcomes in a laboratory with appropriate equipment and personnel that has careful tracking of patient outcomes and corrective mechanisms in place to manage individual operator or laboratory outcome data that fall below national standards. Ensuring that all PCI programs meet appropriate performance metrics is likely to save more lives than requiring all PCI programs have on-site surgery.

RECOMMENDATIONS

1. PCI without on-site surgical backup is being performed with acceptable outcomes and risks in the United States and many other countries. The recommendations outlined in this document are made to ensure patient safety and quality outcomes in such a work environment. This is not an open endorsement of PCI without on-site surgery and we do not support the wide-spread use of PCI without on-site surgery especially in the United States, but acknowledge that this practice may be appropriate in some circumstances.
2. The decision to begin or operate a PCI program without on-site surgical backup should be based on the health needs of a local area, not on desires for personal or institutional financial gain, prestige, market share, or other similar motives. Rural communities may have different health care delivery needs than urban centers and this should be considered.

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

3. It is the goal of SCAI to promote the highest possible program quality. Accordingly, PCI programs both with and without on-site surgical backup must evaluate their outcomes against their countries' benchmark for program performance or other acceptable standard.
4. Operators performing PCI without on-site surgery should perform $\geq$100 total PCIs per year, including $\geq$18 primary PCIs per year. The initial operators at a facility without on-site backup should not begin performing PCI in such facilities until they have a lifetime experience of >500 PCIs as primary operator after completing fellowship. Only operators with complication rates and outcomes equivalent or superior to national benchmarks should perform PCI procedures.
5. Independent program oversight should occur either within the context of a local facility's quality assurance program or through an independent government or external agency. Any program failing to perform adequately should close.
6. Further data collection and analysis should be done to more completely understand the role of PCI without on-site surgical backup as a strategy for the delivery of care.

ATTACHMENT VII

Signed Agreements Between Greenwich Hospital and Yale-New Haven Hospital

Yale-New Haven Heart and Vascular Center Cardiac Services at Greenwich Hospital

I. General Description of the Program

The Yale-New Haven Heart and Vascular Center (YNHHVC) has established and supported the development of cardiac services at Greenwich Hospital for the purpose of improving acute cardiac care to the residents of Connecticut and Westchester County, New York. The initial relationship was established with the implementation of the Primary Angioplasty program in 2005. The YNHHVC with Greenwich Hospital is seeking the development of an Elective Angioplasty program at Greenwich Hospital to be part of an expanded cardiac program at Greenwich Hospital to include advanced congestive heart failure and management and treatment of peripheral vascular disease. YNHHVC will provide cardiac specialists at Greenwich Hospital. The frequency of YNHHVC physicians' presence at Greenwich Hospital will be determined by patient demand, but the interventional cardiologists will be onsite to ensure 24-hour coverage, 365 days a year. The services will be operated under the license of Greenwich Hospital. The Elective Angioplasty program will be located on the Greenwich Hospital campus on Perryridge Road.

The YNHHVC will provide medical and clinical direction, education, training and management and oversight to ensure the delivery of the highest quality of care. A Medical Director and HVC Patient Services Director from YNHHVC will oversee the global aspects of the cardiac services at Greenwich Hospital. The Directors will work closely with Vice President of the YNHHVC as well as Greenwich Hospital's Director, Section of Cardiology and the Program Director for Cardiology and Medicine to ensure the smooth operation of all aspects of the Cardiac program including Elective Angioplasty.

Participation in the Elective Angioplasty program will be limited to experienced interventional cardiologists who meet or exceed the minimum volume standards put forth in the ACCF/AHA/SCAI guidelines as well as the more stringent guidelines from the SCAI Expert Consensus Document for Percutaneous Coronary Intervention without On-site Cardiac Surgery. All interventional cardiologists will also be required to fulfill all necessary educational and academic criteria to maintain a full-time appointment on the GH Department of Medicine, Section of Cardiology medical staff. Greenwich Hospital will participate in ACC benchmarking registry and D_2B benchmarking.

Responsibilities

YNHHVC is responsible for providing the clinical oversight to the proposed program and for providing training to GH staff. YNHHVC management is responsible for the overall management of the cardiac services at Greenwich Hospital, including the proposed Elective Angioplasty program. YNHHVC involvement provides integration with the YNHHVC to ensure one standard of care across the Yale New Haven Health System. Greenwich Hospital will retain appropriate authorities and responsibilities that are necessary for Greenwich Hospital to comply with Medicare requirements for provider-based status and state licensure. The expectation is that Greenwich Hospital will adhere to and complete same the Competency Based Orientation.

Patient Selection Guidelines

Elective PCI Patient Selection Criteria

Pre-catheterization:
Be undergoing diagnostic cardiac catheterization for suspected coronary artery disease
Be at least 18 years of age
Must not be pregnant

Post catheterization:
Coronary artery disease judged to be clinically and angiographically significant
Ability to perform PCI with equipment available at the local site
Procedure risk judged to be not high (See below)
No need for coronary artery by-pass surgery

High procedural risk criteria are:
PCI of unprotected left main coronary artery
PCI of left coronary circulation lesion in the presence of critical (greater than 70%) unprotected left main coronary artery lesion
Poor left ventricular function (EF less than 25%) and need to perform PCI in a vessel supplying significant myocardium
PCI of single lesion that jeopardizes greater than 50% of viable myocardium

II. Emergency Transfers/Referrals

Elective angioplasty patients from Greenwich Hospital requiring emergency cardiac surgery can be transferred to the nearest cardiac surgery facility or to Yale-New Haven Hospital or Bridgeport Hospital when travel time does not impose a safety risk for the patient. Y-Access will be utilized to ensure ready access.

VI. Joint Quality Assurance Reviews

The program will be consistent with the clinical standards established through the Yale New Haven Heart and Vascular Center. In addition to strict adherence to the American College of Cardiology/American Heart Association (ACCF/AHA/SCAI) guidelines for PCI the proposed program will strive to meet the more stringent guidelines from the SCAI Expert Consensus Document on PCI without On-site Surgical Backup.

YNHHVC will draw on its collective clinical resources and experience to ensure that all of the necessary standards, protocols, policies, procedures and quality assessments are in place prior to the initiation of the elective angioplasty program and that the program staff and physicians are fully educated on these standards and procedures.

Utilization and outcomes data will be tracked by YNHHVC and the Center for Outcomes Research and Evaluation (CORE) and provided to GH on a regular basis for ongoing quality improvement. Quality improvement plans will be developed. The Greenwich Hospital program will be fully integrated into YNHHVC quality improvement activities including monthly morbidity and mortality (M&M) conferences and quality indicators monitoring. The YNHHS Quality Council will also track the elective angioplasty program outcomes. This includes participation in national and state benchmarking projects. Expect participation D_2B quality review and full case review analysis for outliers.

VII. Joint Training

All technical and nursing staff from Greenwich Hospital's Cardiac Catheterization Laboratory participates in an education program consisting of didactic, "one-on-one" observational and hands-on training. Greenwich Hospital staff rotates through the cardiac catheterization laboratory at YNHH, as well as shadow experiences in ICU and CV floor.

Training includes but is not limited to familiarization with: angioplasty equipment (guide catheters, guide wires, and angioplasty catheters including balloons and stents); commonly used drugs, assessment and monitoring anticoagulation, use of intra-aortic balloon equipment, patient transfer and a number of items related to patient care before, during and after the procedure. Participation in HVC Operations Council with issues relevant to the Elective Angioplasty Program.

VIII. Implementation of Agreement

Implementation of the agreement is subject to the receipt of the CON approval from OHCA and an ongoing evaluation of quality and outcomes measures that have been identified by YNHHVC to the program.

The foregoing is agreed to this 27th day of January, 2012.

CPORT- E Trial

Randomized trial comparing medical, economic and quality of life outcomes of non-primary PCI at hospitals with and without on-site cardiac surgery

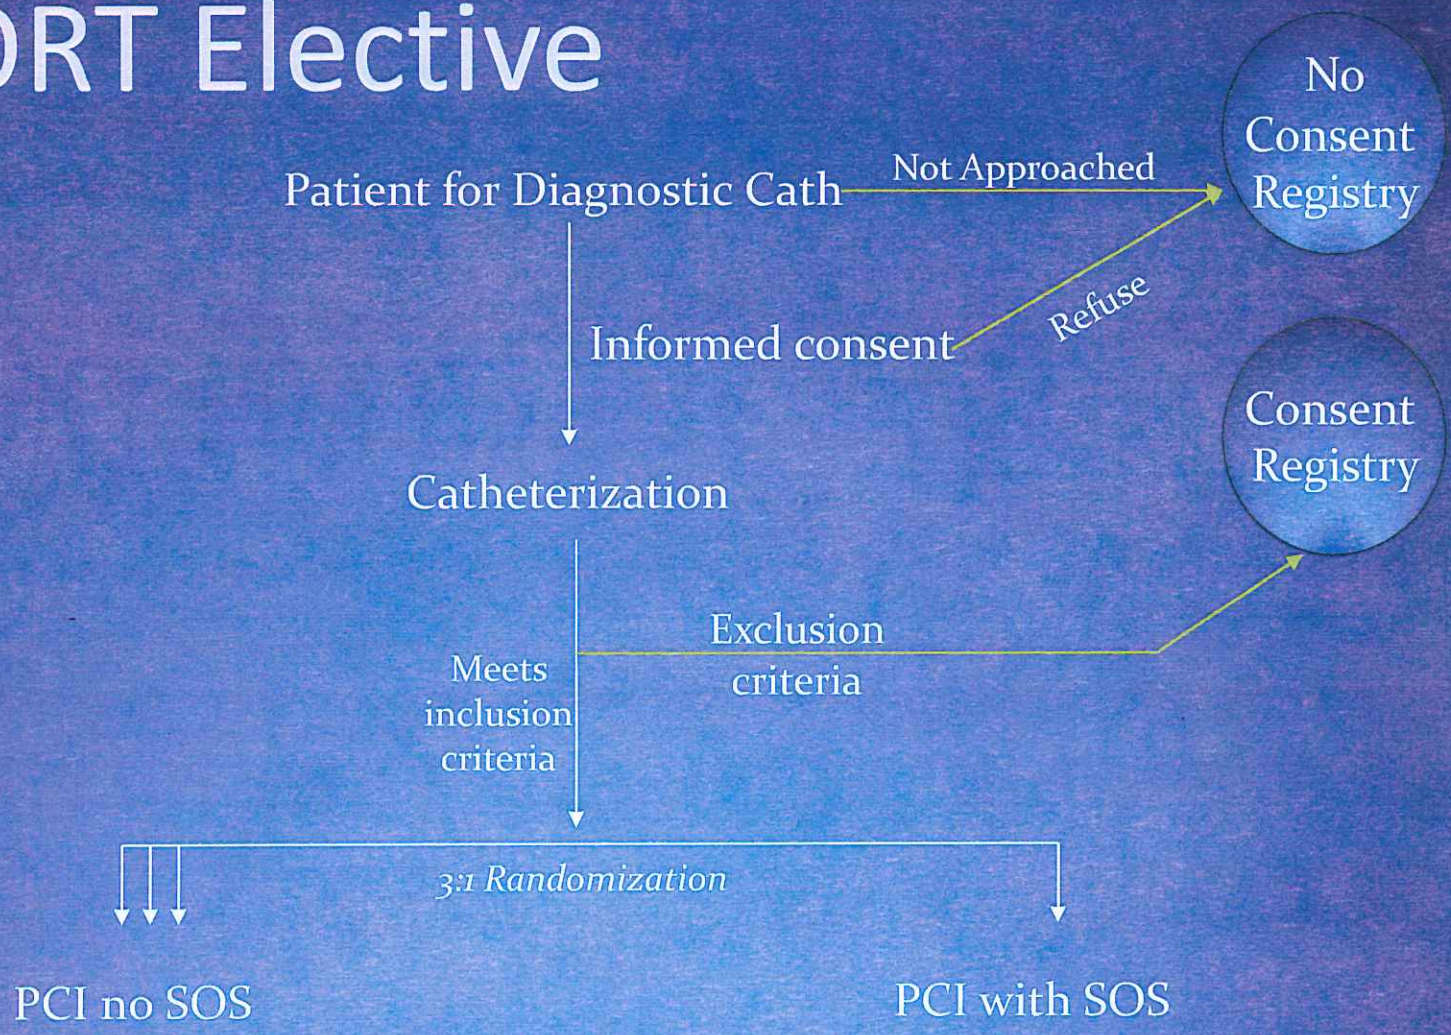
Atlantic C-PORT

Motivation for Trial

- Sustain primary PCI program at no-SOS hospitals
- Improve access to PCI services
- Reduce pressure to create additional cardiac surgery programs
- Need for research to inform healthcare policy decisions by state and national organizations

Atlantic C-PORT

C-PORT Elective



Analysis by intention-to-treat

Atlantic C-PORT

Study Endpoints

- Non-inferiority trial
- Primary Endpoints
  - **All-cause mortality at 6 weeks**
  - MACE at 9 months
    - All-cause mortality
    - Q-wave myocardial infarction
    - Target vessel revascularization
- *Assuming 6 week mortality to be 0.8%, a sample size of **18360** was selected to define a non-inferiority margin of 0.4% with a one-sided test for non-inferiority using α=0.05 and β=0.80 for both primary endpoints.*

Atlantic C-PORT

Inclusion and Exclusion Criteria

Patient

Inclusion

- Age ≥ 18 years
- Informed consent
- ≥ 50% stenosis
- All target lesions approachable at no-SOS hospital

Exclusion

- Unprotected LM
- EF < 20%
- MD-judged high risk

Devices

Inclusion

- Balloon, stent
- Distal protection
- Covered stent
- Cutting balloon - in-stent restenosis

Exclusion

- Atherectomy
- Cutting balloon- de novo lesion

Institution

Inclusion

- ≥ 200 PCI/year
- 24/7 Primary PCI
- Complete formal development program
- Interventionalist meets AHA/ACC competency

	No-SOS (%)	SOS (%)	P-value
CABG	0.48	0.68	0.10
Emergency CABG	0.10	0.22	0.05
Unplanned Cath	4.41	3.35	0.002
Unplanned PCI	2.11	1.32	0.001

Atlantic C-PORT

Summary

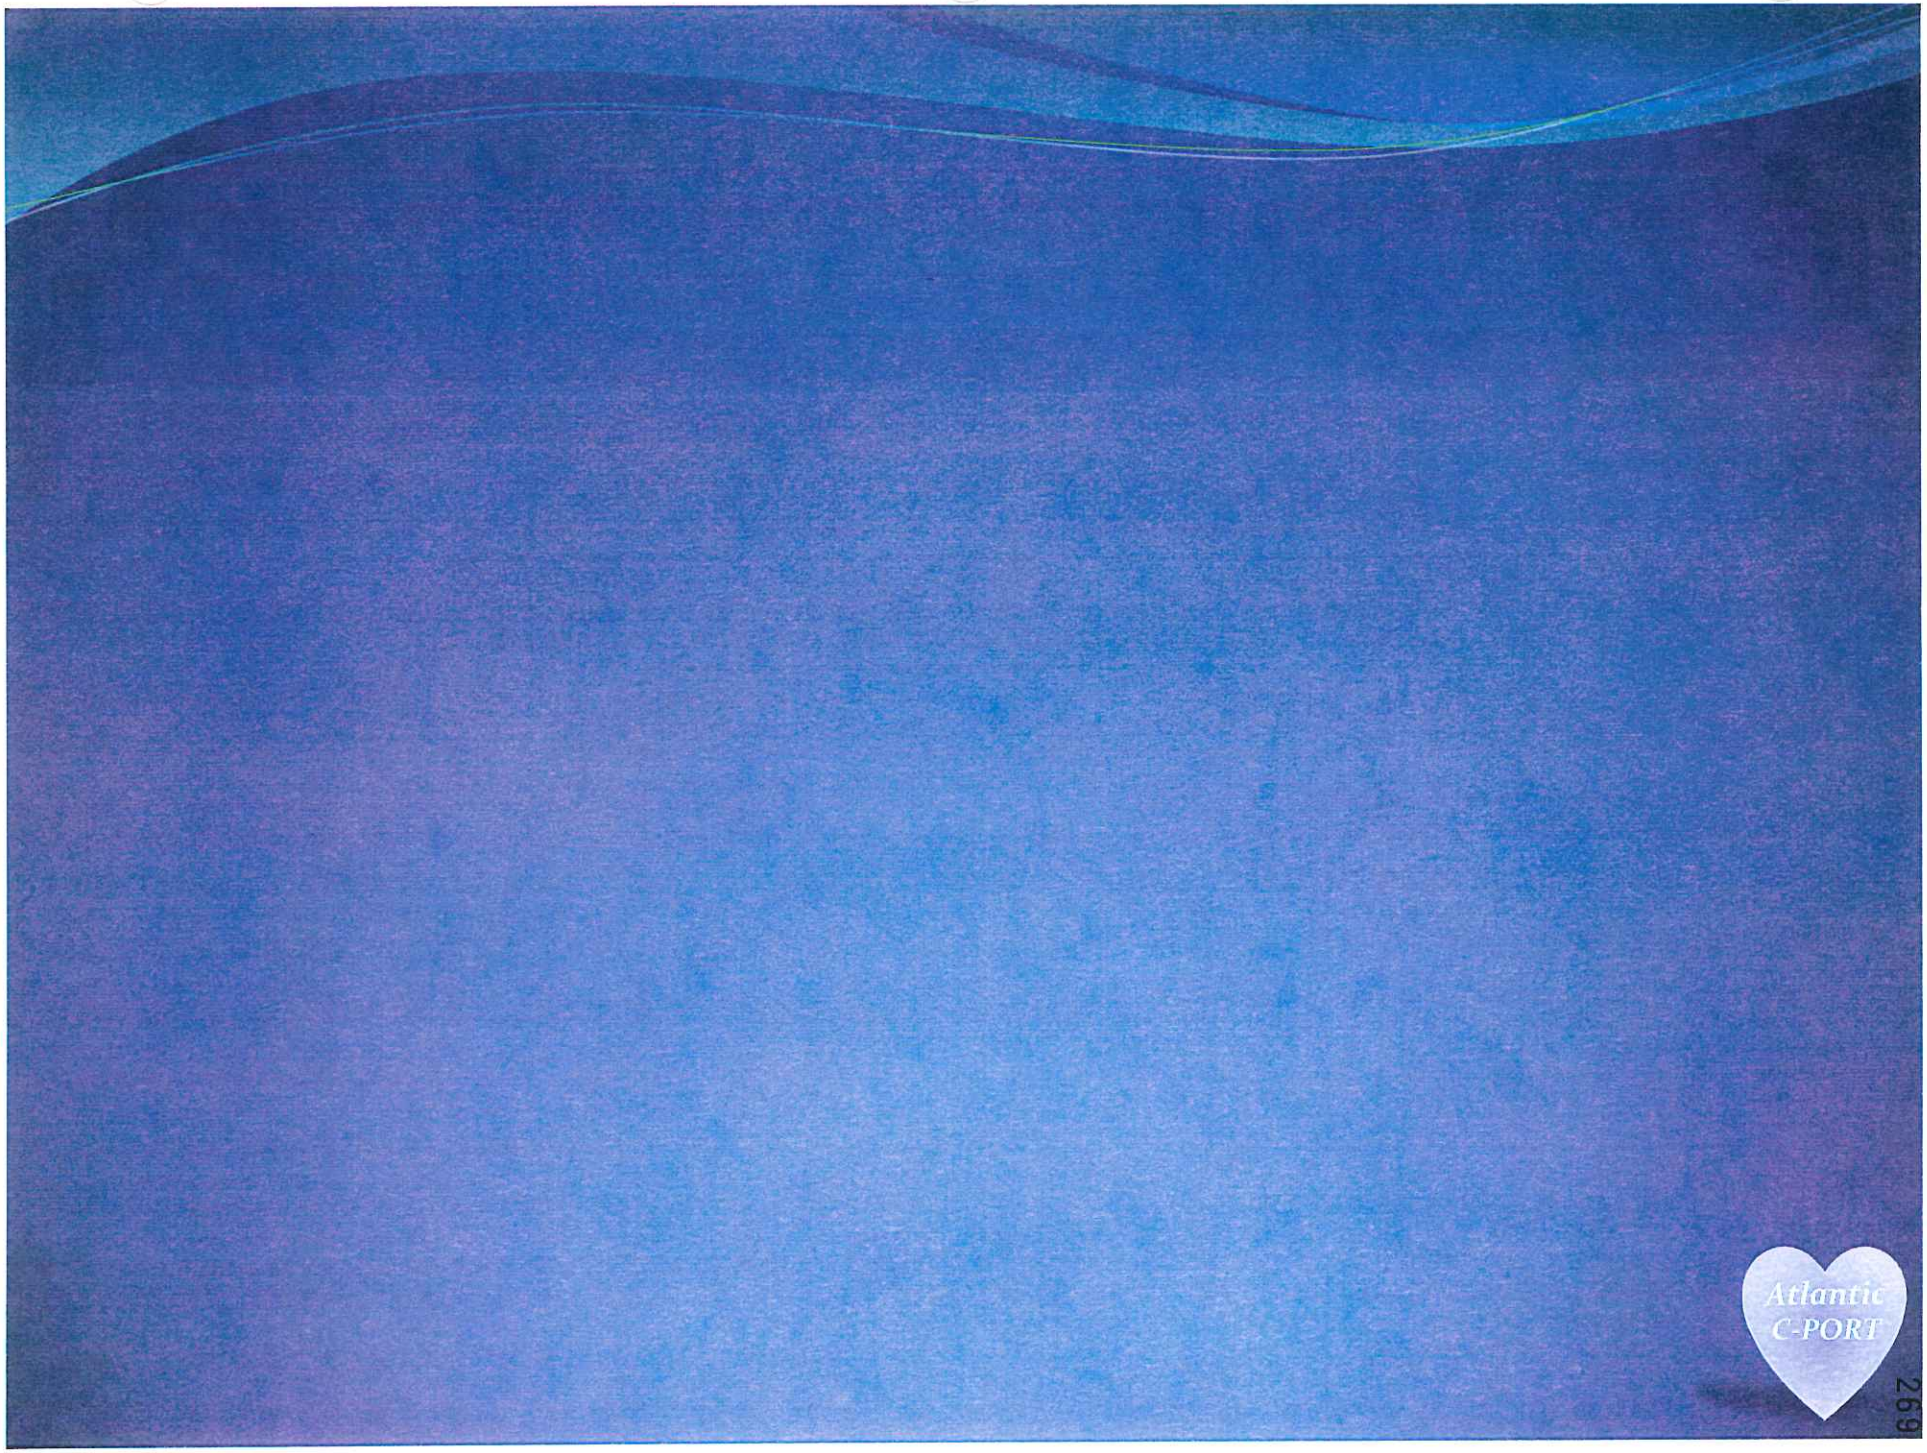
- **PCI success is greater than 90% in both groups but lower in patients randomized to hospitals without surgery on-site**
  (success rate difference of 1.1% on per patient basis; 0.7% on per lesion basis)
- **Number of cath lab visits required to complete the index PCI is greater in patients randomized to hospitals with surgery on-site**
  (1.3 versus 1.7 visits/patient)
- **Unplanned catheterization and PCI procedures are uncommon but occur more frequently in patients randomized to hospitals without surgery on-site**
  (4.4% no-SOS vs 3.4% SOS)
- **Emergency CABG procedures are rare, but occur more frequently in patients randomized to hospitals with surgery on-site**
  (0.1% no-SOS vs 0.2% SOS)
- **Mortality is similar in both groups**
  (0.91% no-SOS vs 0.93% SOS)
- **The incidence of bleeding, vascular repair, stroke and renal failure is similar in both groups**

Atlantic C-PORT

Conclusion

- In hospitals without on-site cardiac surgery that complete a formal PCI development program, adhere to C-PORT participation requirements, and whose outcomes are monitored, non-primary PCI is safe and associated with similar rates of adverse events including mortality.
- Long-term, quality outcome data are currently being collected on these study subjects and will be reported early in 2012.

Atlantic C-PORT



Atlantic
C-PORT

Summary

- **Angiographic Outcomes**
  - PCI Success > 90% in both groups but lower in hospitals without surgery on-site
    (success rate difference of 1.1% on per patient basis; 0.7% on per lesion basis)
  - Number of catheterization laboratory visits required to complete the index PCI is greater in patients randomized to hospitals with surgery on-site
    (1.3 versus 1.7 visits/patient)
- **Unplanned procedure outcomes**
  - Unplanned catheterization and PCI procedures were uncommon but occurred more frequently in patients randomized to hospitals without surgery on-site
    (4.4% no-SOS vs 3.4% SOS)
  - Emergency coronary CABG was rarely required, but was utilized more among patients at hospitals with surgery on-site
    (0.1% no-SOS vs 0.2% SOS)
- **Patient Outcomes**
  - Mortality is similar in both groups
    (0.91% no-SOS vs 0.93% SOS)
  - The incidence of bleeding, vascular repair, stroke and renal failure is similar in both groups

Atlantic C-PORT

Summary

	No SOS (%)	SOS (%)	Relative Difference	Absolute Difference
PCI Success	90.8	91.9	1.2 %	204
Number procedures / index PCI	1.3	1.7	30 %	5570
Unplanned cath or PCI	4.4	3.4	29 %	184
Unplanned emergency CABG	0.10	0.22	50 %	22
Mortality	.91	.93	3.2 %	4
Bleeding	3.4	3	13 %	76

Atlantic C-PORT

Summary - 1

- Historical, angiographic and clinical characteristics of study subjects are similar at hospitals with and without on-site surgery
- Acute coronary syndrome is the most frequent clinical presentation in both groups
- Fewer procedures are classified as "elective" at hospitals without surgery on-site
- PCI success rate differs by less than 1% in the two groups, but is statistically lower at hospitals without on-site surgery
- In patients assigned to hospitals with on-site surgery there are more staged procedures and more catheterization laboratory visits are required to complete the index PCI.

Atlantic C-PORT

Summary - 2

- Six weeks after index PCI
  - Mortality is similar at hospitals with and without SOS
  - Incidence of bleeding, renal failure and stroke are similar at hospitals with and without SOS
  - Unplanned CABG, particularly emergency CABG, are more frequent at hospitals with SOS
  - Unplanned catheterization and PCI procedures are more frequent in patient assigned to no-SOS hospitals

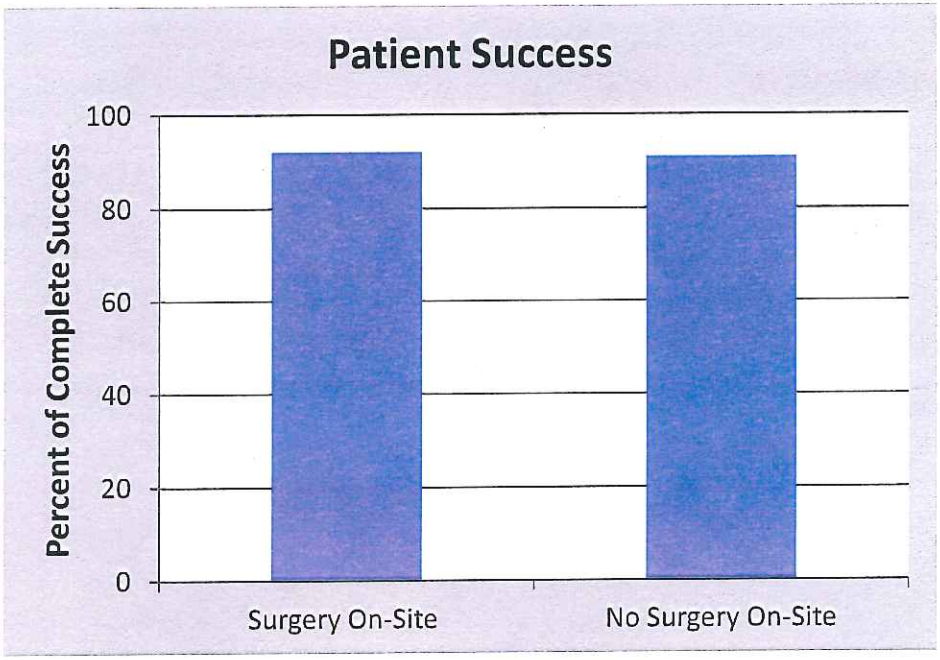
AHA/ASA CPORT-E Trial Summary

CPORT-E Trial

Background: Comparison of the safety and quality outcomes of PCI performed at hospitals with and without on-site cardiac surgery.

Purpose: To determine whether the safety and benefits of angioplasty are the same at hospitals with or without surgery backup. The study is designed to show that there is no detectable difference between the safety and benefits of the procedure at the two types of hospital. Cost is also compared.



Methods: Interventional , randomized, safety/efficacy study, parallel assignment, open label, non-inferiority, health services research (n=18,867 randomized)

Primary Endpoints: Mortality at 6 weeks and MACE = death + MI + TVR at 9 months

Secondary Endpoints: Include emergency CABG; MI; TVR & subsequent TVR; HF & class; Angina & class; stroke; MACE; angiographic complications & success; please see complete listing at clinicaltrials.gov

Results: Mortality and incidence of bleed, vascular repair, stroke and renal failure was comparable in both groups.

Conclusion: Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without cardiac surgery capabilities fared as well as those in hospitals that did. Outcomes at 9 months post procedure will be reported next year.

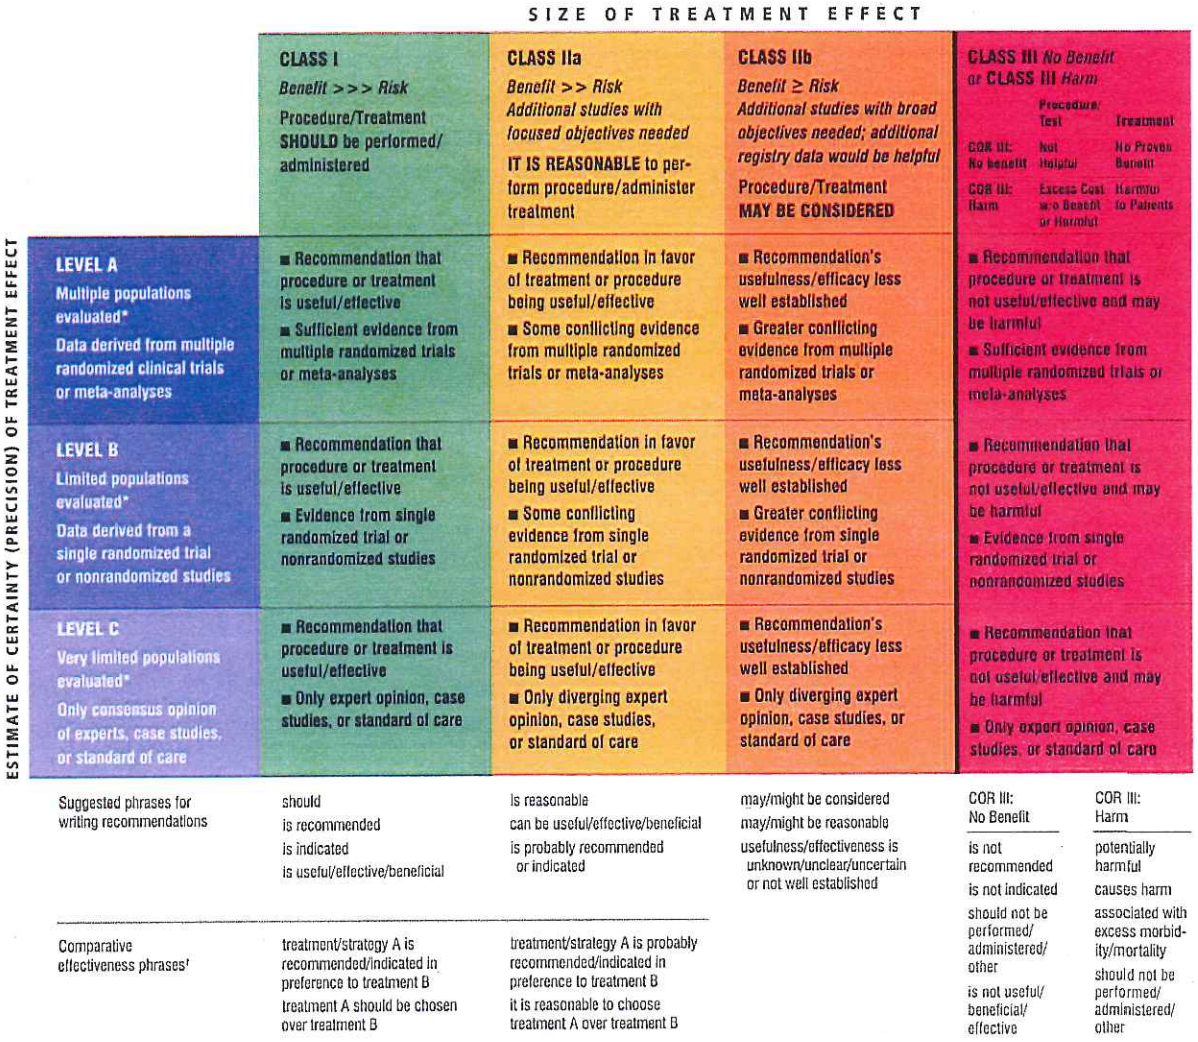
Classification of Recommendations and Levels of Evidence



SIZE OF TREATMENT EFFECT

ESTIMATE OF CERTAINTY (PRECISION) OF TREATMENT EFFECT

	CLASS I *Benefit >>> Risk* Procedure/Treatment **SHOULD** be performed/ administered	CLASS IIa *Benefit >> Risk* *Additional studies with focused objectives needed* **IT IS REASONABLE** to perform procedure/administer treatment	CLASS IIb *Benefit ≥ Risk* *Additional studies with broad objectives needed; additional registry data would be helpful* Procedure/Treatment **MAY BE CONSIDERED**	CLASS III *No Benefit* or CLASS III *Harm* Procedure/ Test / Treatment COR III: No benefit — Not Helpful — No Proven Benefit COR III: Harm — Excess Cost w/o Benefit or Harmful — Harmful to Patients
LEVEL A Multiple populations evaluated* Data derived from multiple randomized clinical trials or meta-analyses	■ Recommendation that procedure or treatment is useful/effective ■ Sufficient evidence from multiple randomized trials or meta-analyses	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Sufficient evidence from multiple randomized trials or meta-analyses
LEVEL B Limited populations evaluated* Data derived from a single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is useful/effective ■ Evidence from single randomized trial or nonrandomized studies	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Evidence from single randomized trial or nonrandomized studies
LEVEL C Very limited populations evaluated* Only consensus opinion of experts, case studies, or standard of care	■ Recommendation that procedure or treatment is useful/effective ■ Only expert opinion, case studies, or standard of care	■ Recommendation in favor of treatment or procedure being useful/effective ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation's usefulness/efficacy less well established ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Only expert opinion, case studies, or standard of care
Suggested phrases for writing recommendations	should is recommended is indicated is useful/effective/beneficial	is reasonable can be useful/effective/beneficial is probably recommended or indicated	may/might be considered may/might be reasonable usefulness/effectiveness is unknown/unclear/uncertain or not well established	COR III: No Benefit: is not recommended; is not indicated; should not be performed/ administered/ other; is not useful/ beneficial/ effective COR III: Harm: potentially harmful; causes harm; associated with excess morbidity/mortality; should not be performed/ administered/ other
Comparative effectiveness phrases†	treatment/strategy A is recommended/indicated in preference to treatment B treatment A should be chosen over treatment B	treatment/strategy A is probably recommended/indicated in preference to treatment B it is reasonable to choose treatment A over treatment B		

A recommendation with Level of Evidence B or C does not imply that the recommendation is weak. Many important clinical questions addressed in the guidelines do not lend themselves to clinical trials. Although randomized trials are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

*Data available from clinical trials or registries about the usefulness/ efficacy in different subpopulations, such as sex, age, history of diabetes, history of prior myocardial infarction, history of heart failure, and prior aspirin use.

†For comparative effectiveness recommendations (Class I and IIa; Level of Evidence A and B only), studies that support the use of comparator verbs should involve direct comparisons of the treatments or strategies being evaluated.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Introduction

The PCI guideline reflects the growth of knowledge in the field and parallels the many advances and innovations in the field of interventional cardiology, including primary PCI, BMS and DES, IVUS and physiologic assessments of stenosis, and newer antiplatelet and anticoagulant therapies. This guideline addresses ethical aspects of PCI, vascular access considerations, CAD revascularization, including hybrid revascularization, revascularization before noncardiac surgery, optical coherence tomography, advanced hemodynamic support devices, no-reflow therapies, and vascular closure devices.

Most of this document is organized according to "patient flow," consisting of preprocedural considerations, procedural considerations, and postprocedural considerations.

The STEMI, PCI, and CABG guidelines were written concurrently, with additional collaboration with the SIHD guideline writing committee, allowing for greater collaboration on topics such as PCI in STEMI and revascularization strategies in patients with CAD.

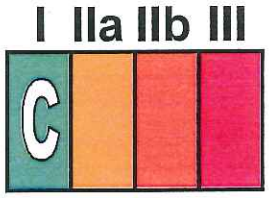
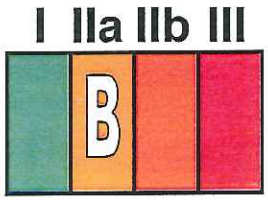
Heart Team Approach to Revascularization Decisions

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Heart Team Approach to Revascularization Decisions



A Heart Team approach to revascularization is recommended in patients with unprotected left main or complex CAD.



Calculation of the STS and SYNTAX scores is reasonable in patients with unprotected left main and complex CAD.

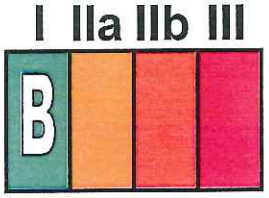
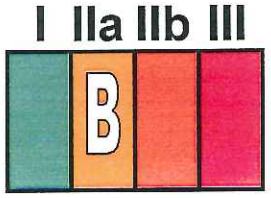
American Heart Association.

SCAI The Society for Cardiovascular Angiography and Interventions

Revascularization to Improve Survival: Left Main CAD Revascularization



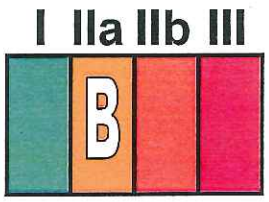
CABG to improve survival is recommended for patients with significant (≥50% diameter stenosis) left main CAD.



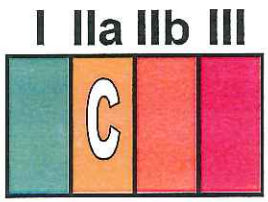
PCI to improve survival is reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: 1) anatomic conditions associated with a low risk of PCI procedural complications and a high likelihood of a good long-term outcome (e.g., a low SYNTAX score [≤22], ostial or trunk left main CAD); and 2) clinical characteristics that predict a significantly increased risk of adverse surgical outcomes (e.g., STS-predicted risk of operative mortality ≥5%).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Left Main CAD Revascularization (cont.)



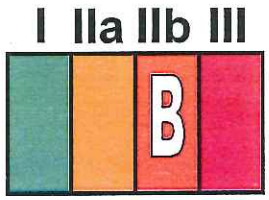
PCI to improve survival is reasonable in patients with UA/NSTEMI when an unprotected left main coronary artery is the culprit lesion and the patient is not a candidate for CABG.



PCI to improve survival is reasonable in patients with acute STEMI when an unprotected left main coronary artery is the culprit lesion, distal coronary flow is TIMI (Thrombolysis In Myocardial Infarction) grade <3, and PCI can be performed more rapidly and safely than CABG.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Left Main CAD Revascularization (cont.)



PCI to improve survival may be reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: 1) anatomic conditions associated with a low to intermediate risk of PCI procedural complications and an intermediate to high likelihood of good long-term outcome (e.g., low-intermediate SYNTAX score of <33, bifurcation left main CAD); and 2) clinical characteristics that predict an increased risk of adverse surgical outcomes (e.g., moderate-severe chronic obstructive pulmonary disease, disability from previous stroke, or previous cardiac surgery; STS-predicted risk of operative mortality >2%).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

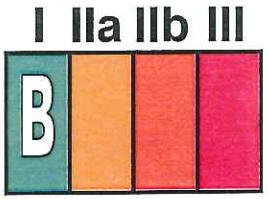
Revascularization to Improve Survival: Left Main CAD Revascularization (cont.)

Harm

PCI to improve survival should not be performed in stable patients with significant (≥50% diameter stenosis) unprotected left main CAD who have unfavorable anatomy for PCI and who are good candidates for CABG.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization



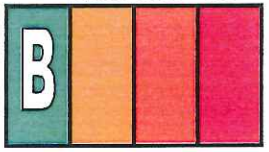
CABG to improve survival is beneficial in patients with significant (≥70% diameter) stenoses in 3 major coronary arteries (with or without involvement of the proximal LAD artery) or in the proximal LAD plus 1 other major coronary artery.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization (cont.)

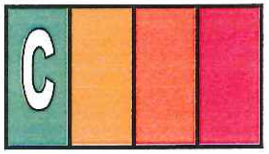
CABG

I IIa IIb III



PCI

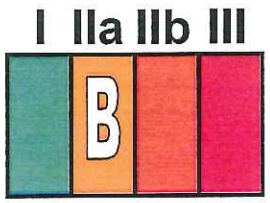
I IIa IIb III



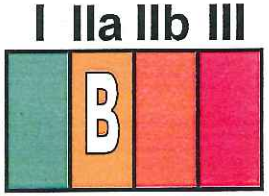
CABG or PCI to improve survival is beneficial in survivors of sudden cardiac death with presumed ischemia-mediated ventricular tachycardia caused by a significant (≥70% diameter) stenosis in a major coronary artery.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization (cont.)



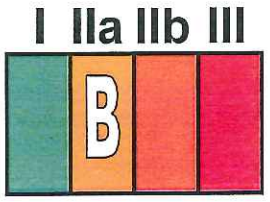
CABG to improve survival is reasonable in patients with significant (≥70% diameter) stenoses in 2 major coronary arteries with severe or extensive myocardial ischemia (e.g., high-risk criteria on stress testing, abnormal intracoronary hemodynamic evaluation, or >20% perfusion defect by myocardial perfusion stress imaging) or target vessels supplying a large area of viable myocardium.



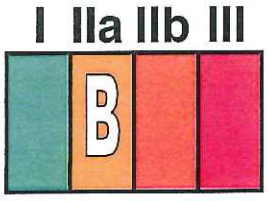
CABG to improve survival is reasonable in patients with mild-moderate left ventricular systolic dysfunction (ejection fraction 35% to 50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal LAD coronary artery stenosis, when viable myocardium is present in the region of intended revascularization.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization (cont.)



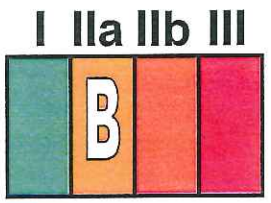
CABG with a LIMA graft to improve survival is reasonable in patients with a significant (≥70% diameter) stenosis in the proximal LAD artery and evidence of extensive ischemia.



It is reasonable to choose CABG over PCI to improve survival in patients with complex 3-vessel CAD (e.g., SYNTAX score >22) with or without involvement of the proximal LAD artery who are good candidates for CABG.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization (cont.)



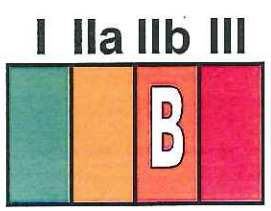
CABG is probably recommended in preference to PCI to improve survival in patients with multivessel CAD and diabetes mellitus, particularly if a LIMA graft can be anastomosed to the LAD artery.

The usefulness of CABG to improve survival is uncertain in patients with significant (≥70%) stenoses in 2 major coronary arteries not involving the proximal LAD artery and without extensive ischemia.

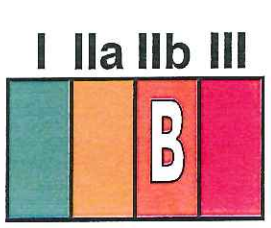
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization (cont.)

The usefulness of PCI to improve survival is uncertain in patients with 2- or 3-vessel CAD (with or without involvement of the proximal LAD artery) or 1-vessel proximal LAD disease.



CABG might be considered with the primary or sole intent of improving survival in patients with SIHD with severe LV systolic dysfunction (EF<35%) whether or not viable myocardium is present.



The usefulness of CABG or PCI to improve survival is uncertain in patients with previous CABG and extensive anterior wall ischemia on noninvasive testing.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Survival: Non-Left Main CAD Revascularization (cont.)

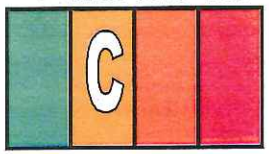
Harm

CABG or PCI should not be performed with the primary or sole intent to improve survival in patients with SIHD with 1 or more coronary stenoses that are not anatomically or functionally significant (e.g., <70% diameter non–left main coronary artery stenosis, fractional flow reserve >0.80, no or only mild ischemia on noninvasive testing), involve only the left circumflex or right coronary artery, or subtend only a small area of viable myocardium.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Symptoms

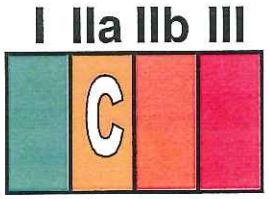
CABG or PCI to improve symptoms is beneficial in patients with 1 or more significant (≥70% diameter) coronary artery stenoses amenable to revascularization and unacceptable angina despite GDMT.



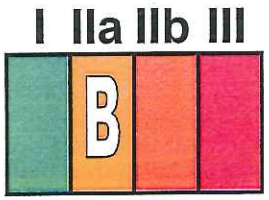
CABG or PCI to improve symptoms is reasonable in patients with 1 or more significant (≥70% diameter) coronary artery stenoses and unacceptable angina for whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Symptoms (cont.)



PCI to improve symptoms is reasonable in patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses associated with ischemia, and unacceptable angina despite GDMT.



It is reasonable to choose CABG over PCI to improve symptoms in patients with complex 3-vessel CAD (e.g., SYNTAX score >22), with or without involvement of the proximal LAD artery who are good candidates for CABG.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Symptoms (cont.)

CABG to improve symptoms might be reasonable for patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses not amenable to PCI, and unacceptable angina despite GDMT.

Transmyocardial laser revascularization performed as an adjunct to CABG to improve symptoms may be reasonable in patients with viable ischemic myocardium that is perfused by arteries that are not amenable to grafting.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Revascularization to Improve Symptoms (cont.)

Harm

CABG or PCI to improve symptoms should not be performed in patients who do not meet anatomic (≥50% left main or ≥70% non–left main stenosis) or physiologic (e.g., abnormal fractional flow reserve) criteria for revascularization.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Dual Antiplatelet Therapy Compliance and Stent Thrombosis

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Dual Antiplatelet Therapy Compliance and Stent Thrombosis

Harm

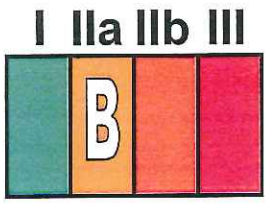
PCI with coronary stenting (BMS or DES) should not be performed if the patient is not likely to be able to tolerate and comply with DAPT for the appropriate duration of treatment based on the type of stent implanted.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Hybrid Coronary Revascularization

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Hybrid Coronary Revascularization



Hybrid coronary revascularization (defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries) is reasonable in patients with 1 or more of the following:

a. Limitations to traditional CABG, such as a heavily calcified proximal aorta or poor target vessels for CABG (but amenable to PCI);

b. Lack of suitable graft conduits;

c. Unfavorable LAD artery for PCI (i.e., excessive vessel tortuosity or chronic total occlusion).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Hybrid Coronary Revascularization (cont.)

Hybrid coronary revascularization (defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries) may be reasonable as an alternative to multivessel PCI or CABG in an attempt to improve the overall risk-benefit ratio of the procedures.

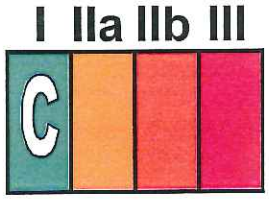
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Preprocedural Considerations

Radiation Safety

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Radiation Safety



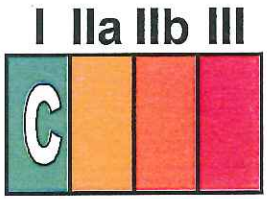
Cardiac catheterization laboratories should routinely record relevant available patient procedural radiation dose data (e.g., total air kerma at the international reference point [$K_{a,r}$], air kerma air product [P_{KA}], fluoroscopy time, number of cine images), and should define thresholds with corresponding follow-up protocols for patients who receive a high procedural radiation dose.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

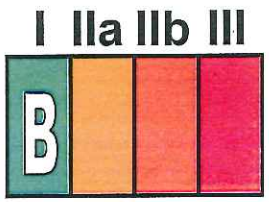
Contrast-Induced Acute Kidney Injury

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Contrast-Induced Acute Kidney Injury



Patients should be assessed for risk of contrast-induced AKI before PCI.



Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration.

In patients with CKD (Crcl <60 mL/min), the volume of contrast media should be minimized.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Contrast-Induced Acute Kidney Injury (cont.)

No Benefit

Administration of N-acetyl-L-cysteine is not useful for the prevention of contrast-induced AKI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Preprocedural Considerations

Anaphylactoid Reactions

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Anaphylactoid Reactions

Patients with prior evidence of an anaphylactoid reaction to contrast media should receive appropriate steroid and antihistamine prophylaxis before repeat contrast administration.

No Benefit

In patients with a prior history of allergic reactions to shellfish or seafood, anaphylactoid prophylaxis for contrast reaction is not beneficial.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Preprocedural Considerations

Statin Treatment

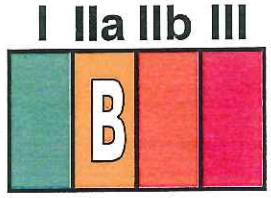
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Statin Treatment

Statin-naive patients:

Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI.

Patients on chronic statin therapy:



Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI.

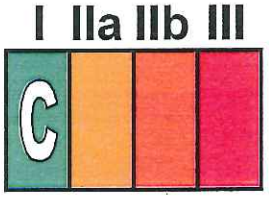
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Preprocedural Considerations

Bleeding Risk

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Bleeding Risk



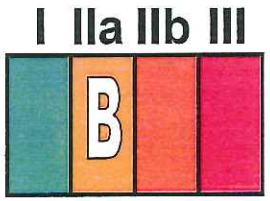
All patients should be evaluated for risk of bleeding before PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Hospitals Without On-Site Surgical Backup

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Hospitals Without On-Site Surgical Backup



Primary PCI is reasonable in hospitals without on-site cardiac surgery, provided that appropriate planning for program development has been accomplished.

Elective PCI might be considered in hospitals without on-site cardiac surgery, provided that appropriate planning for program development has been accomplished and rigorous clinical and angiographic criteria are used for proper patient selection.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Hospitals Without On-Site Surgical Backup (cont.)

Harm

Primary or elective PCI should not be performed in hospitals without on-site cardiac surgery capabilities without a proven plan for rapid transport to a cardiac surgery operating room in a nearby hospital or without appropriate hemodynamic support capabilities for transfer.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Procedural Considerations

Vascular Access

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Vascular Access

The use of radial artery access can be useful to decrease access site complications.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: UA/NSTEMI

An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in UA/NSTEMI patients who have refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: UA/NSTEMI (cont.)

An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in initially stabilized UA/NSTEMI patients (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: UA/NSTEMI (cont.)

The selection of PCI or CABG as the means of revascularization in the patient with ACS should generally be based on the same considerations as those without ACS.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: UA/NSTEMI (cont.)

No Benefit

An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with extensive comorbidities (e.g., liver or pulmonary failure, cancer) in whom

a. The risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization,

b. There is a low likelihood of ACS despite acute chest pain, or

c. Consent to revascularization will not be granted regardless of the findings.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI

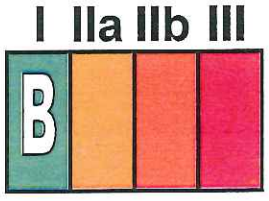
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Coronary Angiography

Strategies in STEMI

A strategy of immediate coronary angiography with intent to perform PCI (or emergency CABG) in patients with STEMI is recommended for

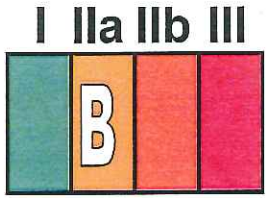
a. Patients who are candidates for primary PCI.



b. Patients with severe heart failure or cardiogenic shock who are suitable candidates for revascularization.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Coronary Angiography Strategies in STEMI (cont.)



A strategy of immediate coronary angiography (or transfer for immediate coronary angiography) with intent to perform PCI is reasonable for patients with STEMI, a moderate to large area of myocardium at risk, and evidence of failed fibrinolysis.

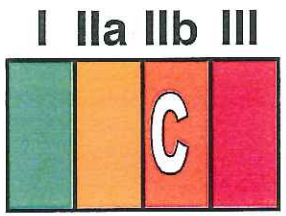
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–
Coronary Angiography Strategies in STEMI (cont.)

A strategy of coronary angiography (or transfer for coronary angiography) 3 to 24 hours after initiating fibrinolytic therapy with intent to perform PCI is reasonable for hemodynamically stable patients with STEMI and evidence for successful fibrinolysis when angiography and revascularization can be performed as soon as logistically feasible in this time frame.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Coronary Angiography Strategies in STEMI (cont.)



A strategy of coronary angiography performed before hospital discharge might be reasonable in stable patients with STEMI who did not undergo cardiac catheterization within 24 hours of STEMI onset.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Coronary Angiography Strategies in STEMI (cont.)

No Benefit

A strategy of coronary angiography with intent to perform PCI is not recommended in patients with STEMI in whom the risks of revascularization are likely to outweigh the benefits or when the patient or designee does not want invasive care.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

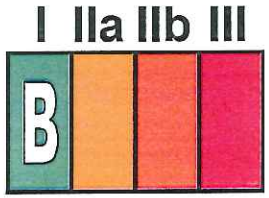
Procedural Considerations

PCI in Specific Clinical Situations: Primary PCI of the Infarct Artery

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Primary PCI of the Infarct Artery

Primary PCI should be performed in patients within 12 hours of onset of STEMI.



Primary PCI should be performed in patients with STEMI presenting to a hospital with PCI capability within 90 minutes of first medical contact as a systems goal.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Primary PCI of the Infarct Artery (cont.)

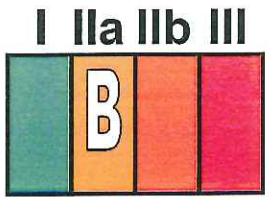
Primary PCI should be performed in patients with STEMI presenting to a hospital without PCI capability within 120 minutes of first medical contact as a systems goal.

Primary PCI should be performed in patients with STEMI who develop severe heart failure or cardiogenic shock and are suitable candidates for revascularization as soon as possible, irrespective of time delay.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Primary PCI of the Infarct Artery (cont.)

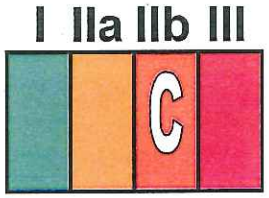
Primary PCI should be performed as soon as possible in patients with STEMI and contraindications to fibrinolytic therapy with ischemic symptoms for <12 hours.



Primary PCI is reasonable in patients with STEMI if there is clinical and/or electrocardiographic evidence of ongoing ischemia between 12 and 24 hours after symptom onset.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: STEMI–Primary PCI of the Infarct Artery (cont.)



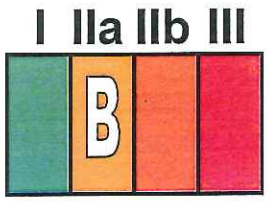
Primary PCI might be considered in asymptomatic patients with STEMI and higher risk presenting between 12 and 24 hours after symptom onset.

Harm

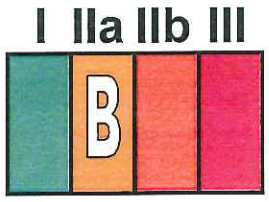
PCI should not be performed in a noninfarct artery at the time of primary PCI in patients with STEMI without hemodynamic compromise.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

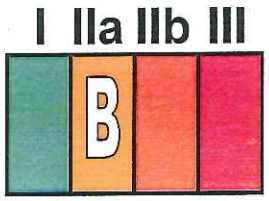
Delayed or Elective PCI in Patients with STEMI



PCI is reasonable in patients with STEMI and clinical evidence for fibrinolytic failure or infarct artery reocclusion.



PCI is reasonable in patients with STEMI and a patent infarct artery 3 to 24 hours after fibrinolytic therapy.



PCI is reasonable in patients with STEMI who demonstrate ischemia on noninvasive testing.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Delayed or Elective PCI in Patients with STEMI

PCI of a hemodynamically significant stenosis in a patent infarct artery >24 hours after STEMI may be considered as part of an invasive strategy.

PCI of a totally occluded infarct artery >24 hours after STEMI should not be performed in asymptomatic patients with 1- or 2-vessel disease if patients are hemodynamically and electrically stable and do not have evidence of severe ischemia.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

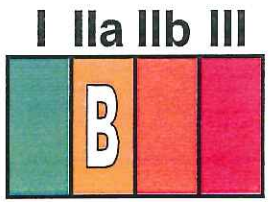
PCI in Specific Clinical Situations: Cardiogenic Shock

PCI is recommended for patients with acute MI who develop cardiogenic shock and are suitable candidates.

A hemodynamic support device is recommended for patients with cardiogenic shock after STEMI who do not quickly stabilize with pharmacologic therapy.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

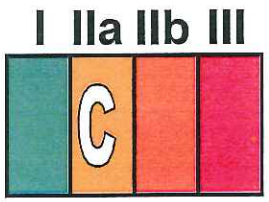
PCI in Specific Clinical Situations: Revascularization Before Noncardiac Surgery



For patients who require PCI and who are scheduled for elective noncardiac surgery in the subsequent 12 months, a strategy of balloon angioplasty, or BMS implantation followed by 4 to 6 weeks of DAPT, is reasonable.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: Revascularization Before Noncardiac Surgery



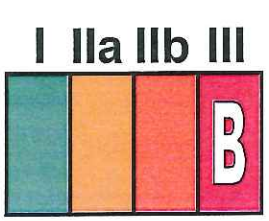
For patients with a DES who must undergo urgent surgical procedures that mandate the discontinuation of DAPT, it is reasonable to continue aspirin if possible and restart the $P2Y_{12}$ inhibitor as soon as possible in the immediate postoperative period.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Clinical Situations: Revascularization Before Noncardiac Surgery

Harm

Routine prophylactic coronary revascularization should not be performed in patients with stable CAD before noncardiac surgery.



Harm

Elective noncardiac surgery should not be performed in the 4 to 6 weeks after balloon angioplasty or BMS implantation or the 12 months after DES implantation in patients in whom the $P2Y_{12}$ inhibitor will need to be discontinued perioperatively.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Procedural Considerations

Coronary Stents

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Coronary Stents

Before implantation of DES, the interventional cardiologist should discuss with the patient the need for and duration of DAPT and the ability of the patient to comply with and tolerate DAPT.

PCI/STEMI

UA/NSTEMI

DES is useful as an alternative to BMS to reduce the risk of restenosis in cases in which the risk of restenosis is increased and the patient is likely to be able to tolerate and comply with prolonged DAPT.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Coronary Stents (cont.)

Balloon angioplasty or BMS should be used in patients with high bleeding risk, inability to comply with 12 months of DAPT, or with anticipated invasive or surgical procedures within the next 12 months during which time DAPT may be interrupted.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Coronary Stents (cont.)

Harm

PCI with coronary stenting should not be performed if the patient is not likely to be able to tolerate and to comply with DAPT.

Harm

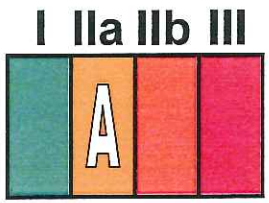
DES should not be implanted if the patient is not likely to be able to tolerate and comply with prolonged DAPT, or this cannot be determined prior to stent implantation.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Adjunctive Diagnostic Devices

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

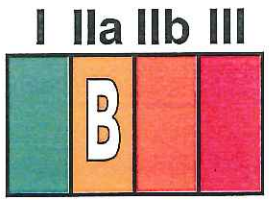
Fractional Flow Reserve



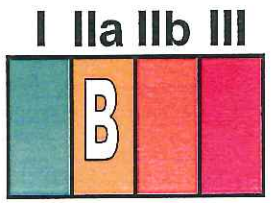
FFR is reasonable to assess angiographic intermediate coronary lesions (50% to 70% diameter stenosis) and can be useful in guiding revascularization decisions in patients with SIHD.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravascular Ultrasound



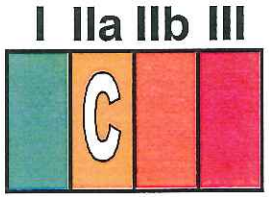
IVUS is reasonable for the assessment of angiographically indeterminate left main CAD.



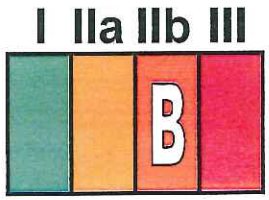
IVUS and coronary angiography are reasonable 4 to 6 weeks and 1 year after transplantation to exclude donor CAD, to detect rapidly progressive cardiac allograft vasculopathy, and to provide prognostic information.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravascular Ultrasound (cont.)



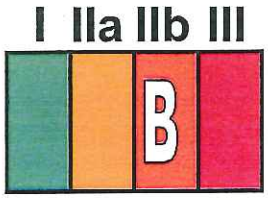
IVUS is reasonable to determine the mechanism of stent restenosis.



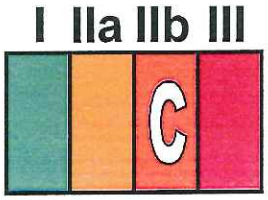
IVUS may be reasonable for the assessment of non-left main coronary arteries with angiographically intermediate coronary stenoses (50% to 70% diameter stenosis).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravascular Ultrasound (cont.)



IVUS may be considered for guidance of coronary stent implantation, particularly in cases of left main coronary artery stenting.



IVUS may be reasonable to determine the mechanism of stent thrombosis.

No Benefit

IVUS for routine lesion assessment is not recommended when revascularization with PCI or CABG is not being contemplated.

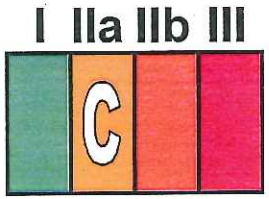
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Procedural Considerations

Adjunctive Therapeutic Devices

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Coronary Atherectomy



Rotational atherectomy is reasonable for fibrotic or heavily calcified lesions that might not be crossed by a balloon catheter or adequately dilated before stent implantation.

No Benefit

Rotational atherectomy should not be performed routinely for de novo or in-stent restenosis.

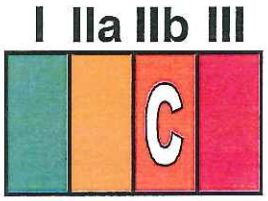
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Thrombectomy

Aspiration thrombectomy is reasonable for patients undergoing primary PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Laser Angioplasty



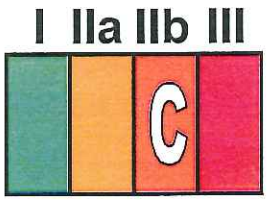
Laser angioplasty might be considered for fibrotic or moderately calcified lesions that cannot be crossed or dilated with conventional balloon angioplasty.

No Benefit

Laser angioplasty should not be used routinely during PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Cutting Balloon Angioplasty



Cutting balloon angioplasty might be considered to avoid slippage-induced coronary artery trauma during PCI for in-stent restenosis or for ostial lesions in side branches.

No Benefit

Cutting balloon angioplasty should not be performed routinely during PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Embolic Protection Devices

Cutting balloon angioplasty should not be performed routinely during PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Percutaneous Hemodynamic Support Devices

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Percutaneous Hemodynamic Support Devices

Elective insertion of an appropriate hemodynamic support device as an adjunct to PCI may be reasonable in carefully selected high-risk patients.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Oral Antiplatelet Therapy

Patients already taking daily aspirin therapy should take 81 to 325 mg prior to PCI.

Patients not on aspirin therapy should be given nonenteric aspirin 325 mg prior to PCI.

After PCI, aspirin should be continued indefinitely.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Oral Antiplatelet Therapy (cont.)

A loading dose of a $P2Y_{12}$ receptor inhibitor should be given to patients undergoing PCI with stenting. Options include:

a. Clopidogrel 600 mg (ACS and non-ACS patients).

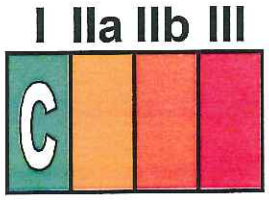
b. Prasugrel 60 mg (ACS patients).

c. Ticagrelor 180 mg (ACS patients).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Oral Antiplatelet Therapy (cont.)

The loading dose of clopidogrel for patients undergoing PCI after fibrinolytic therapy should be 300 mg within 24 hours and 600 mg more than 24 hours after receiving fibrinolytic therapy.



Patients should be counseled on the need for and risks of DAPT before placement of intracoronary stents, especially a DES, and alternative therapies should be pursued if they are unwilling or unable to comply with the recommended duration of DAPT.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Oral Antiplatelet Therapy (cont.)

The duration of $P2Y_{12}$ inhibitor therapy after stent implantation should generally be as follows:

a)In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ inhibitor therapy should be given for at least 12 months. Options include: clopidogrel 75 mg daily, prasugrel 10 mg daily, and ticagrelor 90 mg twice daily.

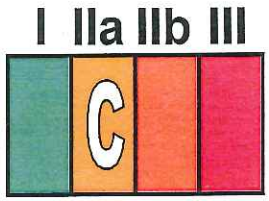
b) In patients receiving a DES for a non–ACS indication, clopidogrel 75 mg daily should be given for at least 12 months if patients are not at high risk of bleeding.

c)In patients receiving a BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Oral Antiplatelet Therapy (cont.)

After PCI, it is reasonable to use 81 mg per day of aspirin in preference to higher maintenance doses.

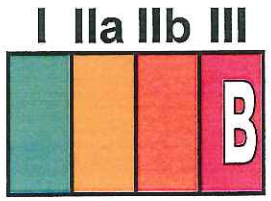


If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of $P2Y_{12}$ inhibitor therapy after stent implantation, earlier discontinuation (e.g., <12 months) of $P2Y_{12}$ inhibitor therapy is reasonable.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Oral Antiplatelet Therapy (cont.)

Continuation of DAPT beyond 12 months may be considered in patients undergoing DES implantation.



Harm

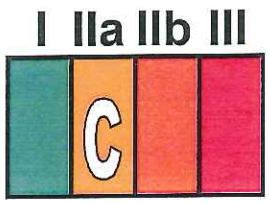
Prasugrel should not be administered in patients with a prior history of stroke or TIA.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravenous Antiplatelet Therapy: STEMI

In patients undergoing primary PCI treated with UFH, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban), whether or not pretreated with clopidogrel.

For GP IIb/IIIa inhibitor administration in patients not pretreated with clopidogrel.



For GP IIb/IIIa inhibitor administration in patients who are pretreated with clopidogrel.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravenous Antiplatelet Therapy : STEMI (cont.)

In patients undergoing primary PCI with abciximab, it may be reasonable to administer intracoronary abciximab.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravenous Antiplatelet Therapy: STEMI (cont.)

No Benefit

Routine precatheterization laboratory (e.g., ambulance or emergency room) administration of GP IIb/IIIa inhibitors as part of an upstream strategy for patients with STEMI undergoing PCI is not beneficial.

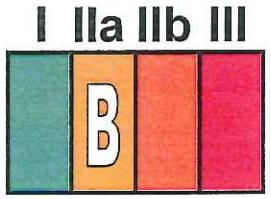
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravenous Antiplatelet Therapy : UA/NSTEMI

In UA/NSTEMI patients with high-risk features (e.g., elevated troponin level) not treated with bivalirudin and not adequately pretreated with clopidogrel, it is useful at the time of PCI to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) in patients treated with UFH.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

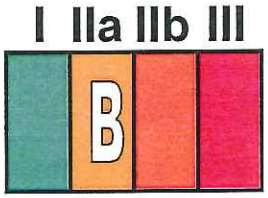
Intravenous Antiplatelet Therapy : UA/NSTEMI (cont.)



In UA/NSTEMI patients with high-risk features (e.g., elevated troponin level) treated with UFH and adequately pretreated with clopidogrel, it is reasonable at the time of PCI to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

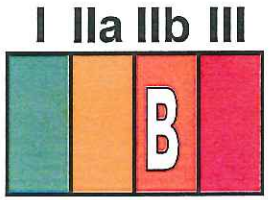
Intravenous Antiplatelet Therapy: SIHD



In patients undergoing elective PCI treated with UFH and not pretreated with clopidogrel, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Intravenous Antiplatelet Therapy: SIHD (cont.)



In patients undergoing elective PCI with stent implantation treated with UFH and adequately pretreated with clopidogrel, it might be reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Antiocoagulant Therapy: Use of Parenteral Anticoagulants During PCI

An anticoagulant should be administered to patients undergoing PCI.

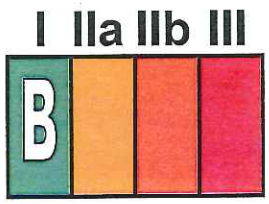
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Antiocoagulant Therapy: UFH

Administration of intravenous UFH is useful in patients undergoing PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Anticoagulant Therapy: Enoxaparin



An additional dose of 0.3 mg/kg intravenous enoxaparin should be administered at the time of PCI to patients who have received <2 therapeutic subcutaneous doses (e.g., 1 mg/kg) or received the last subcutaneous enoxaparin dose 8 to12 hours prior to PCI.

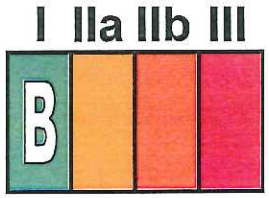
Performance of PCI with enoxaparin may be reasonable in patients either treated with "upstream" subcutaneous enoxaparin for UA/NSTEMI or who have not received prior antithrombin therapy and are administered intravenous enoxaparin at the time of PCI.

UFH should not be given to patients already receiving therapeutic subcutaneous enoxaparin.

Harm

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Antiocoagulant Therapy: Bivalirudin and Argatroban

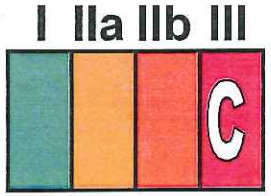


For patients undergoing PCI, bivalirudin is useful as an anticoagulant with or without prior treatment with UFH.

For patients with heparin-induced thrombocytopenia, it is recommended that bivalirudin or argatroban be used to replace UFH.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Antiocoagulant Therapy: Fondaparinux

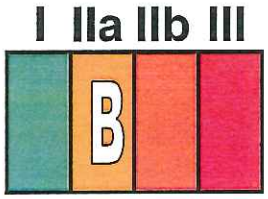


Harm

Fondaparinux should not be used as the sole anticoagulant to support PCI. An additional anticoagulant with anti-IIa activity should be administered because of the risk of catheter thrombosis.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

No-Reflow Pharmacologic Therapies



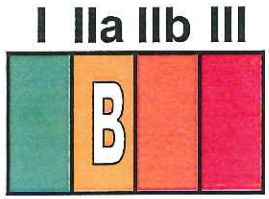
Administration of an intracoronary vasodilator (adenosine, calcium channel blocker, or nitroprusside) is reasonable to treat PCI-related no-reflow that occurs during primary or elective PCI.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Anatomic Situations

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Chronic Total Occlusions



PCI of a CTO in patients with appropriate clinical indications and suitable anatomy is reasonable when performed by operators with appropriate expertise.

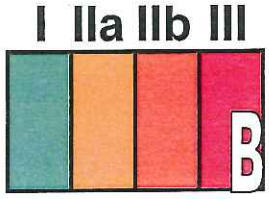
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Saphenous Vein Grafts

EPDs should be used during SVG PCI when technically feasible.

No Benefit

Platelet GP IIb/IIIa inhibitors are not beneficial as adjunctive therapy during SVG PCI.



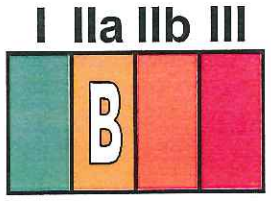
Harm

PCI is not recommended for chronic SVG occlusions.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Bifurcation Lesions

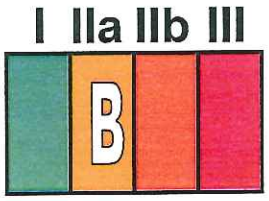
Provisional side-branch stenting should be the initial approach in patients with bifurcation lesions when the side branch is not large and has only mild or moderate focal disease at the ostium.



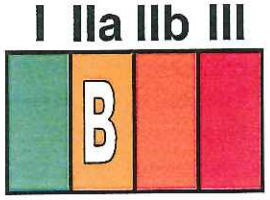
It is reasonable to use elective double stenting in patients with complex bifurcation morphology involving a large side branch where the risk of side-branch occlusion is high and the likelihood of successful side-branch reaccess is low.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Aorto-Ostial Stenosis



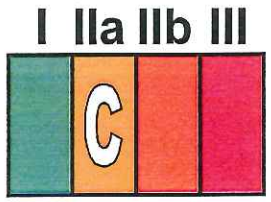
IVUS is reasonable for the assessment of angiographically-indeterminant left main CAD.



Use of DES is reasonable when PCI is indicated in patients with an aorto-ostial stenosis.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Calcified Lesions



Rotational atherectomy is reasonable for fibrotic or heavily calcified lesions that might not be crossed by a balloon catheter or adequately dilated before stent implantation.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PCI in Specific Patient Populations

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Chronic Kidney Disease

In patients undergoing PCI, the glomerular filtration rate should be estimated and the dosage of renally-cleared medications should be adjusted.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Periprocedural Myocardial Infarction Assessment

In patients who have signs or symptoms suggestive of MI during or after PCI, or in asymptomatic patients with significant *persistent* angiographic complications (e.g., large side-branch occlusion, flow limiting dissection, no-reflow phenomenon or coronary thrombosis), creatinine kinase-MB and troponin I or T should be measured.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

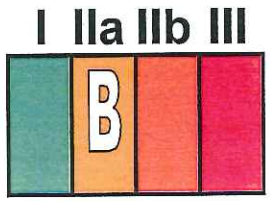
Periprocedural Myocardial Infarction Assessment (cont.)

Routine measurement of cardiac biomarkers (creatinine kinase-MB and/or troponin I or T) in all patients post-PCI may be reasonable.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Vascular Closure Devices

Patients considered for vascular closure devices should undergo a femoral angiogram to ensure anatomic suitability for deployment.



The use of vascular closure devices is reasonable for the purposes of achieving faster hemostasis and earlier ambulation compared with the use of manual compression.

No Benefit

The routine use of vascular closure devices is not recommended for the purpose of decreasing vascular complications, including bleeding.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Postprocedural Antiplatelet Therapy

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Helping Cardiovascular Professionals Learn. Advance. Heal.

American Heart Association.

SCAI The Society for Cardiovascular Angiography and Interventions

Postprocedural Antiplatelet Therapy

After PCI, aspirin should be continued indefinitely.

The duration of $P2Y_{12}$ inhibitor therapy after stent implantation should generally be as follows:

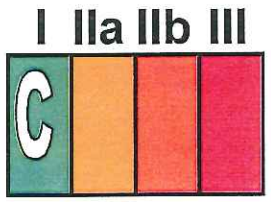
a) In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ inhibitor therapy should be given for at least 12 months (clopidogrel 75 mg daily); prasugrel 10 mg daily; and ticagrelor 90 mg twice daily.

b) In patients receiving a DES for a non–ACS indication, clopidogrel 75 mg daily should be given for at least 12 months if patients are not at high risk of bleeding.

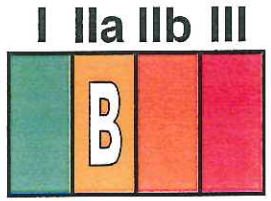
c) In patients receiving a BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks).

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

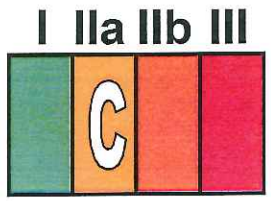
Postprocedural Antiplatelet Therapy (cont.)



Patients should be counseled on the importance of compliance with DAPT, and that therapy should not be discontinued before discussion with the relevant cardiologist.



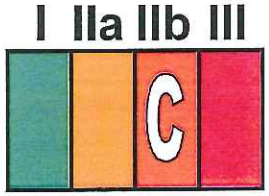
After PCI, it is reasonable to use 81 mg per day of aspirin in preference to higher maintenance doses.



If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of $P2Y_{12}$ inhibitor therapy after stent implantation, earlier discontinuation (e.g., >12 months) of $P2Y_{12}$ inhibitor therapy is reasonable.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Postprocedural Antiplatelet Therapy (cont.)



Continuation of clopidogrel, prasugrel or ticagrelor beyond 12 months may be considered in patients undergoing DES placement.

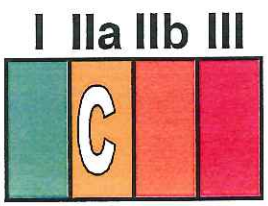
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Proton Pump Inhibitors and Antiplatelet Therapy

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

PPIs and Antiplatelet Therapy

PPI should be used in patients with history of prior GI who require DAPT.



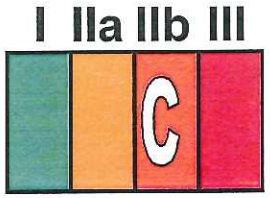
PPI use is reasonable in patients with increased risk of gastrointestinal bleeding (advanced age, concomitant use of warfarin, steroids, nonsteroidal anti-inflammatory drugs, H pylori infection, etc.) who require DAPT.

No Benefit

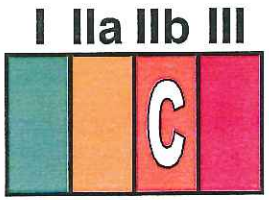
Routine use of a PPI is not recommended for patients at low risk of gastrointestinal bleeding, who have much less potential to benefit from prophylactic therapy.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Clopidogrel Genetic Testing



Genetic testing might be considered to identify whether a patient at high risk for poor clinical outcomes is predisposed to inadequate platelet inhibition with clopidogrel.



When a patient predisposed to inadequate platelet inhibition with clopidogrel is identified by genetic testing, treatment with an alternate $P2Y_{12}$ inhibitor (e.g., prasugrel or ticagrelor) might be considered.

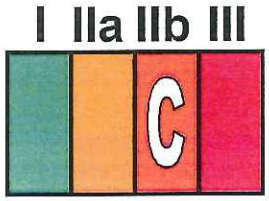
No Benefit

The routine clinical use of genetic testing to screen clopidogrel-treated patients undergoing PCI is not recommended.

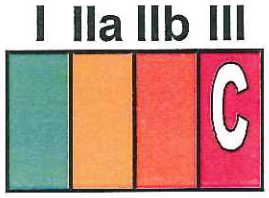
© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Platelet FunctionTesting

Platelet function testing may be considered in patients at high risk for poor clinical outcomes.



In clopidogrel-treated patients with high platelet reactivity, alternative agents, such as prasugrel or ticagrelor, might be considered.



No Benefit

The routine clinical use of platelet function testing to screen clopidogrel-treated patients undergoing PCI is not recommended.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

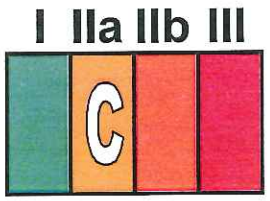
Restenosis

Patients who develop clinical restenosis after balloon angioplasty should be treated with BMS or DES if anatomic factors are appropriate and if the patient is able to comply with and tolerate DAPT.

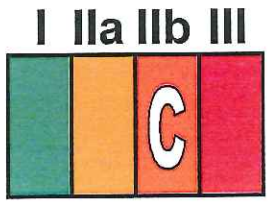
Patients who develop clinical restenosis after BMS should be treated with DES if anatomic factors are appropriate and the patient is able to comply with and tolerate DAPT.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Restenosis (cont.)



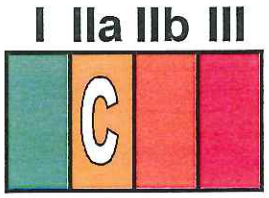
IVUS is reasonable to determine the mechanism of stent restenosis.



Patients who develop clinical restenosis after DES may be considered for repeat PCI with balloon angioplasty, BMS, or DES containing the same drug or an alternative antiproliferative drug if anatomic factors are appropriate and patient is able to comply with and tolerate DAPT.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Exercise Testing



In patients entering a formal cardiac rehabilitation program after PCI, treadmill exercise testing is reasonable.

No Benefit

Routine, periodic stress testing of asymptomatic patients after PCI without specific clinical indications should not be performed.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Cardiac Rehabilitation

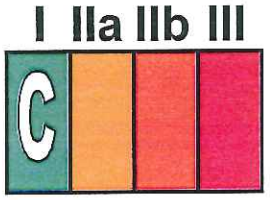
Medically-supervised exercise programs (cardiac rehabilitation) should be recommended to patients after PCI, particularly for moderate- to high-risk patients for whom supervised exercise training is warranted.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

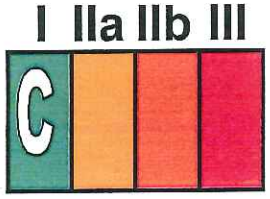
Quality and Performance

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Quality and Performance



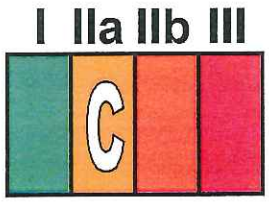
Every PCI program should operate a quality improvement program that routinely: a) reviews quality and outcomes of the entire program; b) reviews results of individual operators; c) includes risk adjustment; d) provides peer review of difficult or complicated cases, and; e) performs random case reviews.



Every PCI program should participate in a regional or national PCI registry for the purpose of benchmarking its outcomes against current national norms.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

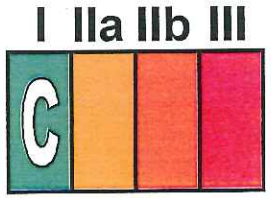
Certification and Maintenance of Certification



It is reasonable for all physicians that perform PCI to participate in the American Board of Internal Medicine interventional cardiology board certification and maintenance of certification program.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Operator and Institutional Competency and Volume



Elective/urgent PCI should be performed by operators with acceptable annual volume (≥75 procedures) at high-volume centers (>400 procedures) with onsite cardiac surgery.

Elective/urgent PCI should be performed by operators and institutions whose current risk-adjusted outcomes statistics are comparable to those reported in contemporary national data registries.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

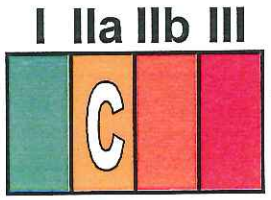
Operator and Institutional Competency and Volume (cont.)

Primary PCI for STEMI should be performed by experienced operators who perform more than 75 elective PCI procedures per year and, ideally, at least 11 PCI procedures for STEMI per year. Ideally, these procedures should be performed in institutions that perform more than 400 elective PCIs per year and more than 36 primary PCI procedures for STEMI per year.

It is reasonable that operators with acceptable volume (≥75 PCI procedures per year) perform elective/urgent PCI at low-volume centers (200 to 400 PCI procedures per year) with onsite cardiac surgery.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

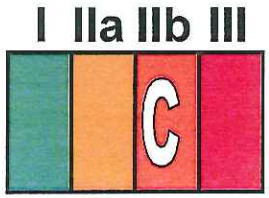
Operator and Institutional Competency and Volume (cont.)



It is reasonable that low-volume operators (<75 PCI procedures per year) perform elective/urgent PCI at high-volume centers (>400 PCI procedures per year) with onsite cardiac surgery. Ideally, operators with an annual procedure volume <75 should only work at institutions with an activity level of more than 600 procedures per year. Operators who perform <75 procedures per year should develop a defined mentoring relationship with a highly experienced operator who has an annual procedural volume of at least 150 procedures per year.

© 2011 by the American College of Cardiology Foundation and the American Heart Association, Inc. All rights reserved.

Operator and Institutional Competency and Volume (cont.)



The benefit of primary PCI for STEMI patients eligible for fibrinolysis when performed by an operator who performs <75 procedures per year (<11 PCIs for STEMI per year) is not well established.

No Benefit

It is not recommended that elective/urgent PCI be performed by low-volume operators (<75 procedures per year) at low-volume centers (200 to 400 procedures per year) with or without onsite cardiac surgery. An institution with a volume of <200 procedures per year, unless in a region that is underserved because of geography, should carefully consider whether it should continue to offer this service.

The Daily Briefing

For PCI, no surgeons required

STUDY: ELECTIVE PCI NO LONGER REQUIRES ON-SITE SURGICAL BACKUP

November 16, 2011

Hospitals without on-site cardiac surgery perform elective percutaneous coronary interventions (PCIs) as safely as facilities that have on-site surgical backup, according to a study presented at the **American Heart Association**'s (AHA) annual meeting.

Each year, nearly one million PCIs are performed in the United States, and most of those cases are non-emergency procedures for patients experiencing chest pain. The AHA and the **American College of Cardiologists** currently recommend that PCI be performed only at hospitals that offer coronary artery bypass grafting procedures. Many states also have criteria for which hospitals can offer PCI.

For the first large study to investigate surgical backup for elective PCI procedures, **Johns Hopkins University** researchers assessed data for 4,500 patients who underwent PCI at hospitals with an available cardiovascular surgeon and 14,000 patients who underwent PCI at hospitals without on-site surgical backup. Hospitals performing the procedure with no surgeon on duty were required to complete special PCI training and perform at least 200 PCI procedures annually.

The study found that success, complication, and death rates did not vary between the two patient groups in the six weeks after the procedure. In addition, surgery was only necessary in 30 cases, and patients at hospitals with no on-site surgical backup were transferred to another facility.

The researchers said they hope the findings provide evidence to policymakers that performing elective PCI at smaller community hospitals is safe. However, they warn that not all hospitals should offer the procedure. "Having the ability to perform elective cases, as well as emergency ones, increases quality that comes with more experience," says Thomas Aversano, the study's lead author.

The findings ultimately may prompt regulatory changes that could effectively decouple PCI and open heart surgery, allowing more flexibility for hospitals pursuing a regionalization strategy (Marchione, *AP/Google*, 11/14; *Medical News Today*, 11/15; Phend, *MedPage Today*, 11/14; Phend, *MedPage Today*, 11/15).

PROFESSIONAL EXPERIENCE

President and Chief Executive Officer	Greenwich Hospital Greenwich, Connecticut	November 1991 - Present
Executive Vice President	Yale New Haven Health System	1998 - Present

Selected Accomplishments:

- Work with Yale New Haven Health System to develop strategic goals and initiatives.
- Facilitated the affiliation with Yale New Haven Health System in 1997.
- Developed a Strategic Plan and Mission Statement in concert with the Board of Trustees, Medical Staff and Community to position Greenwich Hospital for health care delivery in the 21st century.
- Maintained a positive financial position for the institution.
- Aided the Medical Staff in the development of an IPA and developed a hospital-physician partnership.
- Developed integrated approach to health care delivery in the Town of Greenwich.
- Developed and implemented a culture change to the Continuous Quality Improvement philosophy.
- Developed and implemented a communications and community education program.
- Obtained approval from the State of Connecticut for $240 million replacement hospital.
- Developed and opened a free-standing Cancer Center.
- Developed and implemented strategies to increase market share and utilization.
- Led the hospital in its effort to raise $140 million for its Capital Campaign.
- Currently, implementing a plan to effectively downsize and re-engineer the organization to more efficiently deliver higher quality patient care.
- Developed with town government a plan for prevention and wellness.
- Developed a strategic plan with the Board of Directors on affiliations and integration of healthcare.

Chief Operating Officer	Greenwich Hospital	July 1988- November 1991

Selected Accomplishments:

- Responsible for all inpatient and outpatient hospital operations as well as operations of subsidiary corporations of Greenwich Hospital Association Corporation, the Holding Company. These subsidiaries include the following: two walk-in centers, nurse registry, for-profit pharmacy, and real estate company.
- Worked with the President to develop goals and objectives for the hospital and sister corporations in concert with policies set forth by the Board.
- Developed and implemented a marketing and planning department.
- Worked with the Chief Financial Officer in a multi-disciplinary committee structure to reduce accounts receivable by 60 days.
- Developed and implemented a new Quality Assurance, Risk Management Program.
- Worked with the Connecticut Commission on Hospitals and Health Care, the Greenwich Planning and Zoning Commission, and the Building Committee of the Board in preparation for an $117 million renovation and expansion project which includes a free-standing Cancer Center, a 610-car parking garage and modernization of the main hospital.

Chief Operating Officer/Executive Vice President	Our Lady of Mercy Medical Center Bronx, New York	September 1987 - July 1988

Selected Accomplishments:

- Responsible for all inpatient and outpatient hospital operations.
- Worked with the Board of Trustees, Administrative Staff and Medical Staff to develop a strategy for dealing with the nursing shortage.
- Implemented policies and procedures which brought the Medical Center into compliance with new Quality Assurance and Credentialing Regulations.
- Developed a free-standing Department of Emergency Medicine and insured compliance with EMS 911 receiving hospital standards.
- Participated in corporate restructuring plan at Our Lady of Mercy Medical Center in which OLM Holding Company and its subsidiaries were formed.
- Participated in planning and negotiations for acquisition or merger of other health care facilities.

Senior Vice President Professional Services	Our Lady of Mercy Medical Center	July 1986 - September 1987

Selected Accomplishments:

- Worked with Staff to improve clinical departmental operations in order that optimum patient care be delivered in a cost effective efficient way.
- Coordinated application and participated in on-site visit which led to approval of a free-standing residency program in Obstetrics and Gynecology in 1987.
- Developed a program to bring the Institution into compliance with Organ Donation Law.
- Implemented a system of generic screens in the Utilization Review - Quality Assurance departments.
- Developed a working relationship with the Medical Staff in both problem solving an institutional policies and procedures.
- Implemented a guest relations program.

Vice President Medical Support Services	Our Lady of Mercy Medical Center	September 1981 - July 1986

Selected Accomplishments:

- Implemented a computer and case mix management system for Admitting, Medical Records and Utilization Review.
- Designed and implemented a pre-admission testing center.
- Developed a process for effectively dealing with Federal Medicare regulations and Peer Review Organizations.
- Developed policies and strategies which have increased admissions, decreased length of stay and increased efficiency of ancillaries.
- Made numerous educational presentations on all facets of hospital administration at the national, statewide and local level.

Director of Pharmacy and Materials Management	Our Lady of Mercy Medical Center	February 1980 - September 1981

Selected Accomplishments:

- Formulated and implemented a materials management system.
- Coordinated equipment purchase for a $54 million expansion and renovation project.

Director of Pharmacy Services	Our Lady of Mercy Medical Center	February 1979 - February 1980
Asst. Director of Pharmacy Services	Our Lady of Mercy Medical Center	March 1973 - February 1979
Staff Pharmacist	Our Lady of Mercy Medical Center	June 1971 - February 1973

EDUCATION

Fordham University, B.S.	1971
St. John's University, M.S.	1973

FACULTY POSITIONS

New York Medical College - September 1985 - 1990
Clinical Assistant Professor
School of Community and Preventive Medicine

St. John's University - September 1973 - 1988
College of Pharmacy and Allied Health Professions
Affiliated Clinical Professor of Clinical Pharmacy

COMMUNITY AND PROFESSIONAL AFFILIATIONS

- Member - Board of Trustees - Connecticut Hospital Association, 1994 - 2000
- Member - Board of Directors, United Way of Greenwich, 1992 - 1996
- Member - Board of Directors, Boys & Girls Club of Greenwich, 1993 - 1995
- Member - Rotary International, Greenwich Chapter, 1990 - 1994
- Member - American College of Health Care Executives
- Member - Board of Directors, Connecticut Hospital Association Workers' Compensation Trust, 1991 - 1993
- Member of the Board of Pharmacy, Department of Education, State of New York, 1985 – 1988
- Member - Board of Trustees – Norwalk Community College, 2005 to present
- Member – Board of Trustees – Providence Rest Nursing Home, 2003
  Chairman - 2008

EUGENE J. COLUCCI

76 Wilmot Road
Scarsdale, New York 10583
(914) 725-8509

EXPERIENCE

GREENWICH HOSPITAL 1989 to Present
Greenwich, Connecticut

CHIEF FINANCIAL OFFICER

Direct all areas of financial management for a 176-bed acute care facility. These include General Accounting, Budget, Reimbursement, Accounts Receivable, Credit, Collections, Registration, Medical Records, Case Management and Information Systems. Oversee a staff of 225 employees, including the hiring and supervision of management staff. Investigate, plan and monitor areas for new business development. Review investment strategies and develop long and short-term plans to maximize return on assets.

THE MOUNT VERNON HOSPITAL 1985 to 1989
Mount Vernon, New York

CHIEF FINANCIAL OFFICER/CONTROLLER
Direct all aspects of financial management for a 223-bed acute care facility. These include General Accounting, Medical Records, Purchasing, Budget, Reimbursement, Accounts Receivable, Credit, Collections, Admissions and Data Processing Departments. Oversee a staff of 120 employees, including the hiring and supervision of management staff. Investigate, plan and monitor areas for new business development. Review investment strategies and develop long and short-term plans to maximize return on assets.

TOUCHE ROSS & COMPANY 1981 to 1985
New York, New York

AUDIT MANAGER

Supervised financial audits of hospitals. Prepared analyses and reports utilizing various software packages on personal computers. Assisted clients in implemented procedures to ensure collection of detailed financial information.

NEW YORK CITY HEALTH AND HOSPITALS CORP. 1977 to 1981
New York, New York

ASSISTANT DIRECTOR OF REIMBURSEMENT

Coordinated reimbursement reports and third party audits for 18 hospitals and 5 SNFs. Initiated Medicare appeals for cost adjustments.

BLUE CROSS AND BLUE SHIELD 1976 to 1977
New York, New York

AUDITOR

Conducted Blue Cross, Medicaid and Medicare audits on the uniform financial reports.

EDUCATION

ST. JOHN'S UNIVERSITY, Jamaica, New York
M.B.A. - 1979

NIAGARA UNIVERSITY, Niagara Falls, New York
B.B.A. Accounting – 1976

CERTIFICATION

Certified Public Accountant, State of New York – 1984

AFFILIATIONS

American Institute of Certified Public Accountants
New York State Institute of Certified Public Accountants
Healthcare Financial Management Association

SUMMARY OF QUALIFICATIONS

Hospital executive with proven track record achieving operational improvements in a highly competitive environment. Career reflects thirty-five years of progressively responsible positions in all aspects of hospital operations, total quality management, budget and financial performance, strategic planning, policy analysis, program planning and implementation.

PROFESSIONAL EXPERIENCE

Executive Vice President - and Chief Operating Officer — **Greenwich Hospital, Greenwich, Connecticut (174 bed, community teaching hospital, $280 million budget, 1600 employees)** — **2003 – Present**

Senior Vice President - and Chief Operating Officer — **Greenwich Hospital** — **1993 - 2003**

Selected Accomplishments:

- **Reorganized hospital around six service lines; recruited and appointed program directors. Wrote program strategic plans, implemented strategic plans.**
- **Directed hospital re-engineering and redesign process designed to streamline major hospital systems and to significantly reduce hospital costs.**
- **Lead facility program planning effort to construct a 400,000 sq. ft. replacement facility valued at $230 million. Coordinated with finance, legal, zoning and planning.**
- **Supervised new hospital construction; directed activation/occupancy process; facilitated training of physicians, staff and volunteers.**
- **Lead and facilitated service excellence, resulting in patient satisfaction greater than or equal to 98% for nine years.**
- **Installed hospital productivity reporting system with benchmark standards in all operating departments; implemented variable staffing system.**
- **Directed efforts to write mission, vision, values, and goal statements in all operating departments; 650 employees participated in writing departmental mission, vision, values, and goal statements.**
- **Lead interventional cardiology program planning and implementation.**

1991-1993

Executive Vice President - and Chief Operating Officer — **Champlain Valley Physicians Hospital Medical Center, Plattsburgh, New York (420 beds, rural referral center, $66 million budget, 1,500 employees)**

Selected Accomplishments:

- **Developed strategic and operational plan to revitalize Human Resources function; introduced organizational development activities; recruited and appointed Vice President/Human Resources to provide organizational leadership; organized policy/ procedure writing process, and coordinated implementation of two first term union contracts.**

- Directed planning and implementation of hospital-wide managerial/supervisory compensation system, pay practices clarified, and compensation policy and procedure written.

- Implemented hospital-wide team building effort involving nearly 140 department managers and supervisors; directed successful effort to write hospital mission, vision, and values statement linked with 45 department mission, vision, and values statements.

- Built total quality management infrastructure; established and currently implementing four quality management teams who are studying their customers' needs and wants, and what can be done to improve customer satisfaction.

- Organized and directed more than 30 departmental total improvement teams.

- Negotiated hospital based physician contracts that resulted in appropriate renewal terms while maintaining positive medical staff/administration relations.

- Established physician/administrative capital budget committee to review and recommend purchase of capital budget items.

1981 - 1991

Vice President - The Valley Hospital, Ridgewood, New Jersey
(421 beds, $118 million budget, 2,200 employees)

1980 - 1981

Assistant Director - The Valley Hospital, Ridgewood, New Jersey

Selected Accomplishments:

- Organized and managed installation of cardiac surgery/angioplasty program that completed nearly 400 cases in its first year of operation. Program implemented in 139 days.

- Directed planning process for new facilities valued in excess of $45 million; facilities occupied and functioning as planned, included OR, Lab, Radiology, and Obstetrics.

- Planned and implemented four hospital joint ventures that opened a free standing magnetic resonance imaging center - $3.6 million capitalization accomplished through a SEC registered offering.

- Created and organized hospital/medical staff (MeSH) organization; recruited and enrolled 145 physicians representing 14 departments; organized MeSH sponsored preferred provider organization which is available to approximately 6,000 employees and dependents; $650,000 claims first year.

- Recruited and trained new managerial leadership; built management skills; developed managerial training programs, resolved chronic medical staff complaints; improved morale, and reduced turnover rates (14%).

- Directed installation of hospital material management program (actual cost of supplies/admission decreased 1986 vs. 1985).

- Extensive experience working with the medical staff; planned and implemented new medical programs; resolved medical staff concerns.

1975 - 1980

Assistant Vice President - Rhode Island Hospital, Providence, Rhode Island
(719 bed university teaching hospital, 4,000 employees, 250 residents, 60 full time M.D. faculty)

Selected Accomplishments:

- Planned construction of $25 million emergency trauma and operating room facility; wrote role and program specifications.

- Reorganized outpatient clinics into decentralized subsidiary corporation group practices and directed implementation of free standing ambulatory surgery program that serves more than 6,000 patients per year.

1970 - 1973

Staffing Coordinator - Methodist Hospital, St. Louis Park, Minnesota
(475 beds, suburban community hospital)

- Introduced a management engineering based patient classification nurse staffing program with documented savings of $220,000 in first year of operation.

Experience

GREENWICH HOSPITAL GREENWICH, CONNECTICUT
Vice President, Administration **Sept. 2008 - Present**

Responsible for the operations of various clinical and non clinical areas of the hospital. Work closely with the Hospital's Chief Operating Officer and Senior Vice President Health Systems Development on hospital wide projects and initiatives.

Administrative Director, Physical Medicine & Occupational Health Services **Jan. 2004 – Sept. 2008**

Direct an interdisciplinary team of 66 employees across multiple physical locations. Responsible for all operations/finances/program planning over 4 separate cost centers. Set mission/vision over these areas. Scored as a Tier 1 department on employee opinion survey. Improved overall Press Ganey mean scores for areas surveyed from 92.1 to 94.1. Increased outpatient Physical Medicine volume 47%. Initiated implementation of electronic medical record. Wrote business plan which gained board approval for new satellite physical medicine site. Successfully planned for and activated the site. Completed Dale Carnegie, Six Sigma, 21st Century Leadership and Lean Training.

BURKE REHABILITATION HOSPITAL WHITE PLAINS, NEW YORK
Administrator, Rehabilitation Services **Mar. 2002 –Jan. 2004**
(Terence Cardinal Cooke Health Care Center, New York New York)

Manage an Interdisciplinary Department of 37 FTE's (Audiology, Occupational, Physical and Speech Therapy), with a 2 million dollar operating budget. Accountable for all rehabilitation services in a 729-bed, multi-diagnostic Skilled Nursing Facility, and Article 16 Developmental Disabilities outpatient clinic. Specialties include Geriatrics, Short Term Rehabilitation, Dialysis, Huntington's Disease, Alzheimer's Disease, End Stage Pulmonary Disorders, Discrete Units for Residents with AIDS, and an OMRDD governed 50-bed Pediatric Hospital. Reduced overtime and salary costs, improved Medicare/Medicaid compliance, instituted productivity standards, improved performance improvement measures and overall efficiency of the department.

Coordinator Network Development **Jan 2001 – March 2002**

Responsible for the coordination and development of a multi-institutional rehabilitation continuum of care. Implement systems of productivity and outcomes measurement. Coordinate staffing for off site departments. Collaborate with department managers to coordinate consistent treatment protocols, and quality of care standards.

Director of Rehabilitation **Jul. 1999 – Dec. 2000**
(The Wartburg, Mount Vernon New York)

Responsible for the interdisciplinary management of the rehabilitation department including, Audiology, Occupational, Physical, and Speech Therapy. Settings include Sub Acute Rehabilitation, Long Term Care, Adult Day Care, Assisted Living and Outpatient Services. Created and completed performance improvement and quality assurance reports relative to the department. Reviewed and revised policies and procedures to comply with JCAHO, CARF, and DOH standards. Acted as a liaison between staff and administration. Participated on the program evaluation, falls risk, and safety committees. Responsible for creating and monitoring department budget. Worked with MDS coordinator and finance department ensuring that rehabilitation documentation and billing were in compliance with Medicare/Medicaid/PPS guidelines.

Physical Therapy Supervisor **Oct. 1996 – Jul. 1999**

Responsible for the day-to-day operations on a dedicated stroke unit. Acted as a liaison between staff physical therapists and other disciplines. Provided supervision, and acted as a mentor, fostering professional growth and education. Responsible for orienting new staff and for writing scheduled performance evaluations. Completed quality management and research studies specific to the stroke population. Served on the cross training committee and professional advisory committee.

Senior Physical Therapist **Jan. 1996 - Oct. 1996**

Assisted supervisor with daily tasks of unit. Co - Treated with new staff. Instructed multiple physical therapy students. Treated caseload appropriate to the stroke unit employing varied techniques learned from continuing education courses. Wrote evaluations on the performance of physical therapy aides. Conducted research in conjunction with supervisor and physician.

Staff Physical Therapist **May. 1994 - Jan. 1996**

Provided physical therapy care to adult inpatients with various cardiac, orthopedic and neurological disorders. Gave patient and family education lectures on stroke, congestive heart failure, and physical conditioning.

MERCY COLLEGE DOBBS FERRY, NEW YORK

Clinical Faculty **Jan. 1997 - Sept 1998**

Responsible for planning lessons and instructing college level students in kinesiology lab exercises. Assisted in creating and grading examinations.

THE THERAPY RESOURCE CENTER MIDDLETOWN, NEW YORK

Physical Therapist **Apr. 1997 - Feb 1998**

Responsible for the evaluation and treatment of residents at the Richmond Children's Center. Evaluated and treated Clients with Profound Cerebral Palsy. Trained nurses and aides.

HOME THERAPISTS ASSOCIATION ARDSLEY, NEW YORK

Home Care Physical Therapist **Aug. 1994 - Feb. 1995**

Provided home care physical therapy to patients with orthopedic, neurologic, pulmonary, and cardiac disorders. Trained home health aides to care for the clients by following through with written home exercise programs.

EXPERIENCE

2005-Present President and Chief Executive Officer: Yale New Haven Health System (YNHHS)

Yale New Haven Health System is a regional, integrated health care delivery system composed of three local health care delivery networks,as well as a physician foundation, Northeast Medical Group. Anchored by Yale-New Haven Hospital, the Yale-New Haven Children's Hospital, and the Yale-New Haven Psychiatric Hospital totaling 1008-beds, the System includes a Bridgeport network led by the 425-bed Bridgeport Hospital and a Greenwich network anchored by 180-bed Greenwich Hospital. Westerly Hospital (Rhode Island) is a network participant.

Feb. 2012 - Present Chief Executive Officer: Yale-New Haven Hospital and Delivery Network (YNHH)

2005- Feb. 2012 President and Chief Executive Officer: Yale-New Haven Hospital and Delivery Network (YNHH)

Yale-New Haven, a private not-for-profit 1008-bed hospital founded in 1826. It serves as the primary teaching hospital for the Yale University School of Medicine and provides tertiary and quaternary patient care for patients referred, as well as general acute care services for the Greater New Haven metropolitan area.

1993-2005 Executive Vice President & Chief Operating Officer: Yale-New Haven Hospital
Executive Vice President and Secretary: Yale-New Haven Health Services Corporation

Responsible for New Haven Delivery Network operations including Yale-New Haven Hospital operations, finance, human resources and planning and marketing; and Yale-New Haven Ambulatory Services Corporation, which operates two independent surgery centers and a large, full-service radiology business in New Haven and Guilford. Served as the senior Hospital interface for Yale School of Medicine operational issues.

Represented the YNHH Delivery Network in all Health System strategic and operational activities.

1992-1993 Senior Vice President, Administration: Yale-New Haven Hospital
Senior Vice President and Secretary: Yale-New Haven Health Services Corporation

Responsible for Hospital strategic planning and marketing, facilities planning and design, risk management and medicolegal affairs, managed care contracting, Service Quality Improvement, Community Relations, Public Affairs and Engineering.

Project Executive for implementation of Yale-New Haven's $156 million Facilities Renewal Project.

1985-1992 Vice President, Administration: Yale-New Haven Hospital

Responsible for Hospital strategic planning and marketing, facilities planning and design, risk management and medicolegal affairs, managed care contracting, Service Quality Improvement, Community Relations, Public Affairs and Engineering. Provided administrative leadership to Yale-New Haven Health Services Corporation corporate affairs and strategic initiatives.

1984-1985 Assistant Vice President: Yale-New Haven Hospital

Directed the development and implementation of annual Hospital business plan format derived from strategic plan. Completed $6 million renovation of Hospital clinical laboratories. Represented Hospital on underwriting and eligibility and finance activities in malpractice insurance captive.

Dec. 1982-1984 Associate Administrator: Yale-New Haven Hospital

Responsible for Hospital planning activities, including Strategic Planning and general facilities planning and related capital budget activities. Also responsible for Clinical Laboratories ($23 million gross revenue and $11 million expense) and Risk Management and Medicolegal Affairs.

Dec. 1980-Nov. 1982 Assistant Administrator: Yale-New Haven Hospital

Responsible for planning and implementing $11 million renovation program done in concert with major facility replacement project, and for planning and overseeing the move of five major departments and three clinical services (including 80 ICU beds) to a new $73 million facility, during the Spring of 1982. Prepared and presented to the Health Systems Agency and Commission on Hospitals and Health Care, three Certificates of Need; all were approved. Also responsible for Hospital space planning and management, and provided general staff support to the Executive Vice President.

Jan. 1980-Dec. 1980 Administrative Associate: Yale-New Haven Hospital

Provided general staff support to Executive Vice President. Major activities included employee fundraising and campaign to support $73 million facility replacement and renovations program (50% of Hospital employees contributed almost $500,000) and preparation of capital and operating budget materials.

Jan. 1979-Dec. 1980 Administrative Resident: Yale-New Haven Hospital

Summer 1978 Administrative Intern: Alexian Brothers Hospital, San Jose, California

1994	-	1999	Yale New Haven Health Services Corporation
1992	-	1994	Yale-New Haven Hospital
1991	-	1992	Harbor Health Plans
1988	-	1991	Healthcare Venture Associates
1983	-	1988	VHA (Voluntary Hospitals of America)
1977	-	1983	John Hancock Financial Services
1975	-	1976	General Dynamics, Electric Boat Division

PROFESSIONAL EXPERIENCE

Yale-New Haven Hospital
New Haven, Connecticut

As Vice President, Mr. Leary is responsible for clinical program development and physician recruiting with the Yale School of Medicine. He also serves as the Service Line executive for the operation of the Heart & Vascular Center, Organ Transplantation Center and the Level I Trauma Center. These programs are all leading New England providers of tertiary care services.

As Vice President, Physician Development, Mr. Leary was responsible for medical staff outreach to community based physicians and managed medical staff development programs, including computer networking. He restructured the Hospital's diagnostic service privileging and physician reporting systems. The Hospital MDLink Program expanded to 1600 physicians and ancillary staff users. He also served as the Executive Director of the YNHH-Physician Corporation and the Yale-New Haven Community Medical Group with responsibilities for managed care contracting and clinical integration program development.

Yale New Haven Health Services Corporation
New Haven, Connecticut

As Vice President, Mr. Leary was responsible for the Health System's managed care plans and contracting functions. He also managed the system's physician network development programs in primary care and specialty services. Mr. Leary also organized the Health System's central contracting organization. Mr. Leary was responsible for Yale New Haven Health's acquisition of a 50% interest of a 150,000 member PPO plan. He also developed and managed an HMO serving 25,000 Medicaid beneficiaries in Connecticut, as well as a fifty physician primary care group. Mr. Leary also negotiated the sale of the Hospital's interest in a regional HMO.

Yale-New Haven Hospital
New Haven, Connecticut

As Administrative Director, Mr. Leary was responsible for HMO/PPO contracting and payer relations for Yale-New Haven Hospital. He served as Executive Director of its PHO and Medical Staff IPA. Contract revenue exceeded $300 million.

Harbor Health Plans
Mystic, Connecticut

As President, Mr. Leary had overall responsibility for managed care consulting engagements, PPO and workers compensation health plan product development. Mr. Leary founded the company.

Healthcare Venture Associates
Irving, Texas

As a partner in this consulting firm, Mr. Leary was responsible for managed care and physician service programs. Mr. Leary's consulting engagements included HMO turnaround, market development for a leading physician referral service, and physician networking product development for a major communications company.

VHA Physician Services
Irving, Texas

As Vice President, Mr. Leary was responsible for all computer, practice management, and marketing services delivered to over one thousand physicians in twelve network locations. Mr. Leary also created physician network designs for VHA Physician Services hospital clients.

Partners National Health Plans
Irving, Texas

As Vice President of Marketing for this Aetna/VHA joint venture, Mr. Leary was responsible for marketing the Partners' product line including advertising, product development, and national

account sales. Mr. Leary created a 70,000 member PPO for the Teamsters and Partners' National Advantage, the largest hospital PPO in the country.

As Director of Alternative Delivery Systems Consulting, Mr. Leary provided development consulting services to hospitals, medical groups and large employers to create HMOs, PPOs, and other alternative delivery systems.

John Hancock Financial Services
Boston, Massachusetts

As Director of Cost Containment Marketing, Mr. Leary's responsibilities included market management and product development. Mr. Leary helped the company develop its first PPO plan.

As Senior Sales Representative, Mr. Leary was responsible for the sale of $1,000,000 premium accounts. Mr. Leary earned several Production Leader Awards for his efforts.

General Dynamics
Groton, Connecticut

As a Production Planner, Mr. Leary's responsibilities included scheduling, procurement, and materials management for nuclear submarines at the Electric Boat Division.

Board Positions
New England Organ Bank
Board of Trustees, Executive Committee
Waltham, Massachusetts

Hygeia Foundation and Institute for Perinatal Loss and Bereavement
Hygeia Foundation Board
New Haven, CT

CURRICULUM VITAE

Name: Michael Simons, M.D.

Professor with Tenure, Department of Medicine
Traditional Track

Term: *Primary:* with Tenure beginning September 1, 2008

School: Yale University School of Medicine (and the Graduate School)

Education:
B.S. Massachusetts Institute of Technology, Cambridge, MA, June 1980
M.D. *cum laude* Yale University School of Medicine, New Haven, CT, June 1984

Career/Academic Appointments:

1984-1985	Intern in Internal Medicine, New England Medical Center, Boston, MA
1985-1986	Resident in Internal Medicine, New England Medical Center, Boston, MA
1986-1989	Medical Staff Fellow, NIH, NHLBI, Bethesda, MD
1987-1989	Postdoctoral Fellow, Laboratory of Molecular Cardiology, NIH, NHLBI, Bethesda, MD
1989-1991	Fellow in Cardiology, Beth Israel Hospital, Boston, MA
1990-1993	Associate Scientist, Program for Excellence in Molecular Biology of the Cardiovascular System, MIT, Cambridge, MA
1991 - 1993	Instructor in Medicine, Harvard Medical School, Boston MA
1993 - 1997	Assistant Professor of Medicine, Harvard Medical School, Boston MA
1997 - 2001	Associate Professor of Medicine, Harvard Medical School, Boston MA
2001 – 2008	A.G. Huber Professor of Medicine, Dartmouth Medical School, Lebanon NH
2002 – 2008	Professor of Pharmacology & Toxicology, Dartmouth Medical School, Lebanon NH
2008 - Present	Professor with Tenure, Yale University School of Medicine
2008 - Present	Robert W. Berliner Professor of Medicine, Yale University School of Medicine
2008 - Present	Honorary Professor of Medicine, University College London, London, UK
2009 - Present	Professor of Cell Biology, Yale University School of Medicine

Administrative Positions:

2008 – Present	Chief, Section of Cardiovascular Medicine, Yale University School of Medicine
2006 - 2008	Director, Cardiovascular Center, Dartmouth-Hitchcock Medical Center
2003 - 2006	Associate Chair of Medicine for Research, Dartmouth-Hitchcock Medical Center
2001 - 2008	Chief of Cardiology, Dartmouth-Hitchcock Medical Center
2001 - 2008	Director, Angiogenesis Research Center, Dartmouth Medical School
1996 - 2001	Director, Angiogenesis Research Center, Beth Israel Hospital/BIDMC
1995 - 1999	Director, Morse Coronary Care Unit, Beth Israel Hospital/BIDMC
1993 - 2001	Attending Cardiologist, Beth Israel Hospital/BIDMC
1993 - 2001	Associate in Medicine, Beth Israel Hospital/BIDMC

Board Certification:

National Board of Medical Examiners, 1985
Diplomate, American Board of Internal Medicine, 1987
Diplomate, ABIM, Subspecialty of Cardiovascular Disease, 1991, re-certified 2001
Diplomate, Certification Board of Nuclear Cardiology, 1996

Professional Honors & Recognition

A) International/National/Regional

2010	Chair, Keystone Conference Angiogenesis in Health and Disease
2009	Chair, Gordon Research Conference on Vascular Biology
2005-2006	President, North American Vascular Biology Organization
2005	Excellence in Cardiovascular Science Award, AHA Northeast
2005	Elected member, Association of American Physicians (AAP)
2004	Elected member, Association of University Cardiologists (AUC)
2002	Fellow (elected), CV Section, American Physiological Society
2001	Fellow (elected), Basic Science Council, AHA
1999-2003	Established Investigator, American Heart Association
1999	Honorary Citation, Cardiovascular Society of India
1998	Fellow (elected), ATVB Council, AHA
1998	Elected Member, American Society for Clinical Investigations (ASCI)
1995	Honorary Citation, Japanese Circulation Society
1991-1996	Clinician-Scientist of the American Heart Association
1984	A. Richman Research Award of the American College of Chest Physicians

B) University

2005	Excellence in Teaching Award, Department of Medicine, Dartmouth
1986	Teaching Resident Award, Tufts University School of Medicine
1984	Cum Laude, Yale University School of Medicine

Grant History:
A) Current Grants

Agency	Leducq Foundation
Program:	Transatlantic Network
Title:	ARTEMIS Network
PI:	Michael Simons MD & Peter Carmeliet, Ph.D.
Percent effort:	20%
Direct costs for project period	$5,400,000
Project period	9/1/09-8/31/2014

Agency:	NIH/NHLBI
I.D.#	R01 HL62289
Title:	Syndecan function in endothelial cells
P.I.:	Michael Simons, M.D.
Percent effort:	20%

Direct costs per year (last year): $388,563
Total costs for project period: $1,877,013
Project period: 10/01/2008 – 11/30/2013

Agency: NIH/NHLBI
I.D.# R01 HL53793
Title: Angiogenesis and ischemia
P.I.: Michael Simons, M.D.
Percent effort: 20%
Direct costs per year: $322,382
Total costs for project period: $1,711,524
Project period: 06/16/2008 – 05/30/2013

Agency: NIH/NHLBI
ID#: R01 HL084619
Title: Arteriogenesis and arterial branching
P.I.: Michael Simons, M.D.
Percent effort: 20%
Direct costs per year: $316,875
Total costs for project period: $1,637,287
Project period: 07/01/2007 – 06/30/2011

Agency: NIH/NHLBI
I.D.# P50 HL084945
Title: Molecular determinants of pulmonary arterial hypertension
P.I.: Laura Nofke, MD
Role on the project: Co-PI
Percent effort: 5%
Direct costs per year: $49,270
Total costs for project period: $197,080
Project period: 01/01/2007 – 12/31/2010

Agency: NIH/NHLBI
I.D.# HL069948
Title: Mechanism of PAI-1-induced anti-angiogenesis
P.I.: Mary Jo Mulligan-Kehoe, Ph.D.
Role on the project: Co-PI
Percent effort: 5%
Direct costs per year: $9,300
Total costs for project period: $37,200
Project period: 12/01/2007 – 11/30/2011

B) Past Grants

Agency: NIH/NHLBI
I.D.# R13 HL093922A
Title: NAVBO workshop: biology of signaling in the cardiovascular system
P.I.: Michael Simons MD and Timothy Hla, PhD (dual PI)
Percent effort: 0%

Direct costs per year: $15,000
Total costs for project period: $15,000
Project period: 09/01/2008 – 08/31/2009

Agency: NIH/NHLBI
I.D.# R01 HL53793
Title: Angiogenesis and ischemia
P.I.: Michael Simons, M.D.
Percent effort: 25%
Direct costs per year: $213,341
(Last funding year)
Total costs for project period:
Project period: 08/01/1997 – 08/31/2008

Agency: NIH/NHLBI
I.D.# R01 HL62289
Title: Syndecan function in endothelial cells
P.I.: Michael Simons, M.D.
Percent effort: 25%
Direct costs per year (last year): $225,000
Total costs for project period:
Project period: 05/01/1999 – 06/18/2008

Agency: NIH/NHLBI
I.D.# R01 HL070247
Title: Peptide regulators of angiogenesis
P.I.: Michael Simons, M.D.
Percent effort: 25%
Direct costs per year: $249,915
Total costs for project period: $999,600
Project period: 04/01/2002 – 03/31/2006

Agency: NIH/NHLBI
I.D.# P50 HL63609
Title: Endothelial signaling and cardiac angiogenesis
P.I.: Michael Simons, M.D.
Percent effort: 25%
Total costs for project period: $5,884,895
Project period: 04/01/2000 – 03/31/2005

Agency: NIH/NHLBI
I.D.# P50 HL56993
Title: Stimulation of coronary angiogenesis with bFGF
P.I.: Lewis Cantley, Ph.D
Role on the grant: Project PI
Percent effort: 25%
Total costs for project period:
Project period: 04/01/1997 – 03/31/2002

Agency: Scleroderma Research Foundation
I.D.# Investigator Grant

Title:	Angiogenic defects in scleroderma
P.I.:	Michael Simons, M.D.
Percent effort:	0%
Total costs for project period:	$160,000
Project period:	04/01/2005 – 03/31/2008

Agency:	American Heart Association
I.D.#	Established Investigator Grant
Title:	Inflammation and angiogenesis
P.I.:	Michael Simons, M.D.
Percent effort:	25%
Total costs for project period:	$300,000
Project period:	01/01/1999 – 12/31/2003

Agency:	American Heart Association
I.D.#	Clinician-Scientist Award
Title:	Molecular control of restenosis
P.I.:	Michael Simons, M.D.
Percent effort:	75%
Total costs for project period:	$175,000
Project period:	07/01/1991 – 06/30/1996

Lectures, Courses, Web-based Education:

Courses:

2006-2008	Leader, Vascular biology curriculum, Program in experimental molecular medicine
2005-2008	Receptors Course, Department of Pharmacology, Dartmouth
2005	Vasculata Course, Dartmouth College
2004	Vasculata Course, University of Washington
2001	Dartmouth-Hitchcock Cardiology Course

Grand Rounds/Medical School Lectures:

2009	Cardiology Grand Rounds, MGH, Boston, MA
2009	Cardiovascular Research Center Seminar, MGH, Boston, MA
2009	Cardiology Grand Rounds, NYU, NY, NY
2009	Visiting Professor, CBVR, BIDMC, Boston, MA
2009	Cardiovascular Seminar, University of Connecticut
2009	Molecular Biology & Biochemistry Seminar, Mayo Clinic, Rochester, MN
2009	NIH TARP Vascular Biology Seminar, NIH, Bethesda, MD
2009	Cardiology Grand Rounds, University of Massachusetts
2009	Cardiology Grand Rounds, University of Pennsylvania
2009	Cardiovascular Seminar, University of Pennsylvania
2008	Medicine Grand Rounds, Yale University School of Medicine
2008	Vascular biology seminar, Institute of Ophthalmology, University College, London, UK
2008	Seminar, Institute for Cardiovascular Sciences, UCL, London, UK
2008	Cardiology seminar, University of Hawaii, Honolulu, HI
2007	Vascular biology seminar, Yale University School of Medicine
2006	Plenary lecturer, University of North Carolina Vascular Biology Day
2006	Medicine Grand Rounds, University of Rochester, Rochester, NY
2006	Cardiovascular Research Center Seminar, MGH, Boston, MA

2006	Cardiovascular Center Seminar, University of Rochester, Rochester, NY
2005	Vascular Biology Seminar, Emory University
2005	Seminar, Sol Sherry Thrombosis Center, Temple University School of Medicine
2005	Medicine Grand Rounds, University of Texas, Houston
2005	Cell Biology & Biochemistry seminar, University of Texas, Houston
2005	Cardiology Grand Rounds, University of California San Francisco
2005	Cardiology Grand Rounds, Dartmouth Medical School
2004	Medicine Grand Rounds, Dartmouth Medical School
2004	Lecturer, ECM Society, Okayama University School of Medicine
2004	Cardiology Grand Rounds, Yale University School of Medicine
2004	Barry Zaret Symposium, Yale University School of Medicine
2003	Vascular Biology Seminar, University of Washington
2003	Research Seminar, British Heart Foundation/University College London
2003	CARIM Seminar, University of Maastricht School of Medicine
2003	Cardiology Grand Rounds, The University of Chicago
2003	Cardiology Grand Rounds, New England Medical Center
2002	Surgery Grand Rounds, Dartmouth Medical School
2002	ICVBM Seminar, Indiana University School of Medicine
2001	Medicine Grand Rounds, Dartmouth Medical School
2001	Cardiology lecturer, Chiba University, Chiba, Japan
2000	Hematology seminar, NYU School of Medicine
2000	Cardiology Research Seminar, Albert Einstein College of Medicine
2000	Cardiology Grand Rounds, University of California, Irvine
2000	Cardiology Grand Rounds, NYU School of Medicine
2000	Cardiology Grand Rounds, Massachusetts General Hospital
2000	Cardiology Grand Rounds, Dartmouth Medical School
2000	Cardiology Grand Rounds, College of Physicians & Surgeons, Columbia University
1999	Vascular Biology Seminars, Harvard University
1999	Physiology Research Seminar, University of Wisconsin
1999	Physiology Research Seminar, University of Iowa
1999	Medical Grand Rounds, UC Davis Medical Center
1999	Medical Grand Rounds, BIDMC
1999	Cardiology Research Grand Rounds, New England Medical Center
1998	Vascular Biology Seminars, Harvard University
1998	Cardiovascular Research Seminars, St. Elizabeth Hospital
1998	Cardiovascular Grand Rounds, Brigham and Women's Hospital
1997	Cardiovascular Grand Rounds, Northwestern University School of Medicine
1997	Cardiology Grand Rounds, University of Calgary School of Medicine
1996	TCT Conference, Washington, DC, Invited Speaker
1996	Cardiovascular Grand Rounds, Albert Einstein College of Medicine
1995	Nuclear Medicine Grand Rounds, JPNM, Harvard University
1995	Cardiovascular Research Seminars, St. Elizabeth Hospital
1995	Cardiology Grand Rounds, Yamaguchi University School of Medicine, Japan
1995	Cardiology Grand Rounds, University of Montreal, Notre Dame Hospital
1994	Physiology Research Seminar, Texas A&M University
1994	Cardiology Grand Rounds, New York University
1993	Physiology Research Seminar, University of Vermont
1993	Pathology Research Seminar, Beth Israel Hospital
1993	Department of Physiology, Southwestern University School of Medicine
1993	Cardiology Grand Rounds, University of Montreal, Notre Dame Hospital
1992	Nephrology Research Seminar, Beth Israel Hospital

Regional, National and International Contributions:

2009	Speaker and Session Chair, TCT 2009, San Francisco, CA
2009	Speaker, Vesalius Research Center Symposium, KU Leuven, Belgium
2009	CRT 2009, Washington, DC, Invited Speaker
2008	Kloster Seeon 5th International Angiogenesis conference, Kloster Seeon, Germany. Invited Speaker
2008	Biology of signaling in cardiovascular system. NAVBO workshop. Cape Cod, MA. Chair and organizer
2008	Angiogenesis in cancer and other diseases. University of Helsinki symposium. Invited Speaker, Helsinki, Finland.
2008	EECPS/Leopoldina symposium, Bad Nauheim, Germany, Invited speaker
2008	The US-Japan cooperative cancer research program invitational meeting, Kyoto, Japan
2007	USA-France NIH/INSERM Vascular Biology invitational meeting, Paris, France
2007	European Vascular Biology and Microcirculation Conference, Plenary lecturer, Heidelberg, Germany
2007	European Society of Cardiology meeting, Invited Speaker, Vienna, Austria
2007	ESH Conference on Angiogenesis, Albufiera, Portugal, Invited speaker
2007	5th International Proteoglycans conference, Invited speaker, Rio de Janeiro, Brazil
2006	USA-France NIH/INSERM Vascular Biology invitational meeting, Denver, CO
2006	State-of-the-Art lecture, International Vascular Biology Meeting, Amsterdam, NL
2006	Plenary lecture, ATVB Conference, Denver, CO
2006	Nature Biotechnology Conference, Invited Speaker, Miami, FL
2006	Frontiers in Cardiology, Invited Speaker, Munich, Germany
2006	Detours'Sils '06, Invited Speaker, Sils-Maria, Switzerland
2005	NHLBI Arteriogenesis Panel, Bethesda, MD
2005	International Society for Heart Research, Invited Speaker, New Orleans, LA
2005	Gordon Conference on Vascular Biology, Invited Speaker, Ventura Beach, CA
2005	CRT 2005 Meeting. Associate Course Director, Washington, DC
2005	Association of University Cardiologists, Invited Speaker, Phoenix, AZ
2005	AHA Scientific Sessions. Session Chair and Invited Speaker, Dallas, TX
2005	ACC Annual meeting, Invited Speaker, Orlando, FL
2004	PULSE 2004 University of Crete and Hellenic Cardiovascular Society, Invited Speaker, Crete, Greece
2004	NIH Workshop on Trans-institute Angiogenesis Program, Towson, MD
2004	Molecular Imaging, Invited Speaker, Bethesda, MD
2004	International Society for Differentiation, Invited Speaker, Honolulu, HI
2004	Cardiovascular Revascularization Therapy, Invited Speaker ,Washington, DC
2004	2nd International Gene Therapy Conference, Invited Speaker, Osaka, Japan
2003	XXX Argentine Cardiovascular Society Meeting, Invited Speaker, Buenos Aires
2003	XIII International Atherosclerosis Society Mtg, Invited Speaker, Kyoto, Japan
2003	TCT Symposium, Washington, DC, Plenary lecture
2003	Japanese Circulation Society, Fukuoka, Japan, Invited Speaker
2003	International Society for Heart Research, Invited Speaker, Newport, CT
2003	Heart Failure Society of America, Invited Speaker, Las Vegas, NV
2003	Gordon Conference on Angiogenesis, Invited Speaker, Newport, RI
2003	EB2003, Invited Speaker
2003	ACC Annual Meeting, Chicago, IL, Invited Speaker
2002	TCT Symposium, Washington, DC, Plenary lecture
2002	Society of Vascular Surgery, Boston, Invited Speaker

2002	Society of Vascular Biology & Medicine, Boston, Invited Speaker
2002	Keystone Conference on Angiogenesis, Banff, Canada, Invited Speaker
2002	International Vascular Biology Meeting, Kuruizawa, Japan, Invited Speaker
2002	International Society for Heart Research, Landmark Lecture
2002	European PCR 2002 Meeting, Paris, France. Invited Speaker
2002	ACC Annual meeting, Atlanta, GA, Invited Speaker
2002	6th Invitational meeting of the American Society of Nuclear Cardiology
2002	3rd Annual Conference on Atherosclerosis, Thrombosis and Vascular Biology, Salt Lake City, NV, Invited Speaker
2002	2nd Interdisciplinary Euroconference on Angiogenesis, Cascais, Portugal, Invited Speaker
2001	VII World Congress on Microcirculation, Sydney, Australia, Invited Speaker
2001	TCT Symposium, Washington, DC, Invited Speaker
2001	Keystone Conference, Angiogenesis and Chronic Disease, Keystone, CO, Invited speaker
2001	Japanese Cardiovascular Society Annual Meeting, Kyoto, Japan, Invited Speaker
2001	Indian Interventional Society Meeting, Bombay, India, Plenary lecture
2001	Cardiology Frontiers Conference, Tokyo, Japan, Invited Speaker
2001	Angiogenesis & DMR, Washington, DC, Invited Speaker
2001	ACC Annual meeting, Orlando, FL, Invited Speaker
2000	Research Seminar, Proctor & Gamble, Inc.
2000	Research Seminar, Genentech, Inc.
2000	Research Seminar, Biogen, Inc.
2000	Research Initiatives Conference in Vascular Disease, Invited Speaker
2000	Plenary lecturer, XXI Congresso Da Sociedade de Cardiologia Do Estado DeSao Paolo, Campos do Jordao
2000	NIH/NSF Technology Assessment Panel, member
2000	International Society for Vascular Biology, Geneva, Invited Speaker
2000	Guidant Angiogenesis & DMR Workshop, Invited Speaker
2000	European Cardiovascular Society, Amsterdam, Session Chair & Invited Speaker
2000	EB2000, Plenary lecture
2000	EB2000, Featured research symposium, Invited Speaker
2000	Angiogenesis experts panel/Expert forum in bio-interventional cardiology
2000	Angiogenesis & DMR Symposium, Invited Speaker
2000	AHA Symposium and Angiogenesis and DMR, Meeting Co-Chair
2000	ACC Mini-symposium, Invited Speaker
2000	1st R. Ross Memorial Conference, Ulm University, Germany, Invited Speaker
1999	TCT Conference, Invited Speaker
1999	Plenary lecture, Cardiac Society of India, New Delhi, India
1999	Medical University of Beijing, Beijing, China, Invited Speaker
1999	International Society for Heart Research, Invited Speaker
1999	Guest lecturer, Madras and Bombay, India
1999	EPIC Course, Emory University, Invited Speaker
1999	ACCIS Symposium, Plenary Speaker
1999	ACC Minicourse, Invited Speaker
1999	3rd International Seminar on Cardiovascular Biology and Medicine, Pamplona, Spain, Invited Speaker
1999	2nd Annual meeting, International Institute for Research, Co-Chair
1999	2nd Angiogenesis & DMR Symposium, Invited Speaker
1998	Update in Cardiology, University of Toronto, Invited Speaker
1998	TCT Conference, Invited Speaker

1998	Schering Workshop on Angiogenesis, Invited Speaker
1998	Merck Research Labs, Invited Speaker
1998	Gordon Research Conference on Proteoglycans, Invited Speaker
1998	Cleveland Clinic Foundation Mini-Symposium on Angiogenesis, Invited Speaker
1998	4th Local Drug Delivery Conference, Geneva, Switzerland, Invited Speaker
1997	Philip T. Goldenberg Lecture St. Francis Hospital, University of Connecticut
1997	NIH Workshop on Antisense Therapeutics, Invited Speaker
1997	Bristol Myers Squibb Symposium on Promotion of Angiogenesis as Therapy for Cardiovascular Disease, Invited Speaker
1996	NHLBI Workshop on Current Directions in Ischemic Heart Disease, Invited Speaker
1996	Fireside seminar, ACC Annual Meeting, Invited Speaker
1996	2nd International Symposium on Local Cardiovascular Drug Delivery, Invited Speaker
1995	Plenary lecture, Japanese Circulation Society Annual Meeting, Nagoya, Japan
1995	Joint Program in Nuclear Medicine, Harvard University, Invited Speaker
1995	First International Symposium on Local Cardiovascular Drug Delivery, Invited Speaker
1995	Boston Biomedical Research Institute, Invited Speaker
1995	AFCR Featured Research Symposium, Invited Speaker
1994	Program of Excellence in Molecular Biology Meeting, Santa Barbara,
1994	Merck Research Labs, Invited Speaker
1994	Hewlett-Packard Medical Advisory Board Meeting, Invited Speaker
1994	Eighth International Workshop on Future Directions in Interventional Cardiology, Santa Barbara, CA, Invited Speaker
1994	Cell cycle workshop, NHLBI, NIH, Invited Speaker
1993	Society of Experimental Pathology, Invited Speaker
1993	Seventh International Workshop on Future Directions in Interventional Cardiology, Santa Barbara, CA, Invited Speaker
1993	Restenosis Summit, Cleveland Clinic, Invited Speaker
1993	New York Cardiovascular Society, Invited Speaker

PROFESSIONAL SERVICE

Peer Review Groups/Grant Study Sections

2009	Chair, Special Emphasis panel ZRG CVS-F02, NIH
2008	Member, Special emphasis panel ZRG1 CVS D02, NIH
2003-2007	Member, Vascular Cell Molecular Biology Study Section, NIH
1998-2003	Ad hoc member, PPG and SCOR Study section, NIH
1995-2000	National referee, VA Merits Grants Program
1997-1999	Panel Member, US Civilian Research and Development Foundation

Journal Service

2008- Present	Editorial Board, *Circulation Genetics*
2006- Present	Editorial Board, *Circulation*
2005- Present	Editorial Board, *American Journal of Physiology: Heart & Circulatory Physiology*
2004- Present	Editorial Board, *Circulation Research*
1999 - 2003	Editorial Board, *American Journal of Physiology: Heart & Circulatory Physiology*
1998-2007	Editorial Board, Vascular Pharmacology
1993-Present	Reviewer for *American Journal of Pathology; Atherosclerosis; Arteriosclerosis, Thrombosis and Vascular Biology; Circulation; Circulation Research; Developmental Cell, FASEB Journal; Journal of Biological*

Chemistry; Journal of Cell Biology; Journal of Cell Science; Journal of Clinical Investigations; Journal of Leukocyte Biology; Journal of Molecular and Cellular Cardiology; Journal of Nuclear Medicine; Journal of Pathology; Microcirculation; Nature; Nature Medicine; Nature Biotechnology; Nature Cell Biology; New England Journal of Medicine; PNAS; Science

Professional Organizations

North American Vascular Biology Organization (NAVBO)

2003- 2007	Member, NAVBO Council
2003- 2004	Secretary-Treasurer
2005- 2006	President

Meeting Planning/Participation

2010	Chair & Organizer, Keystone conference on angiogenesis
2009	Chair & Organizer, Gordon Research Conference on Vascular Biology
2008	Chair & Organizer, NAVBO workshop on Cardiovascular Signaling
2007	Vice-Chair, Gordon Research Conference on Vascular Biology
2007	Program Committee Chair, Vascular Biology '07 national meeting
2005	Chair and organizer, Vasculata annual conference
2004	Chair and organizer, Angiogenesis: basic science to clinical reality, Dartmouth Science Day conference
2001	Co-chair and organizer, AHA conference on angiogenesis
2001-present	Transcatheter Therapeutics Conference (TCT), Abstract selection committee
1997-present	American College of Cardiology, Abstract Selection Committee
1996-present	American Heart Association, Abstract selection committee

Yale University School of Medicine

2008-Present	Steering Committee, Vascular Biology & Therapeutics Program

Main Medical Center Research Institute

2006- Present	Chair, External Advisory Board

Dartmouth College/Dartmouth Medical School

2002-2008	Dartmouth Advanced Imaging Center Steering committee
2004-2008	Dartmouth-Philips Research Steering committee
2006-2008	Dean's Advisory Board
2006-2008	Clinical chairs committee
2004-2008	Executive Committee, Program in Experimental Molecular Medicine
2002-2006	Dean's committee on translational research

Dartmouth-Hitchcock Medical Center

2006 - 2008	Board of Governors
2006 - 2008	Senior Leadership Committee
2004 - 2008	Web Oversight Committee

Beth Israel Hospital/Beth Israel-Deaconess Medical Center

1998 - 2001	Technology Transfer Committee
1997 - 1999	Clinical Practice Assessment Committee
1996 - 1999	Chair, Institutional Animal Care and Utilization Committee
1995 - 1999	Critical Care Committee

1995 - 1999	Quality Assurance Committee
1995 - 1999	Cardiovascular Practice Guidelines
1995 - 1999	Patient Care Committee

Public Service

2004-2008	Data Safety Monitoring Board, NHLBI, NIH
2004-2006	Advisory Board, FDA

Papers in Press

CURRICULUM VITAE

HENRY S. CABIN, M.D., F.A.C.C.

Address: Home: 154 Peck Hill Rd.
Woodbridge, CT 06525

Office: Yale University School of Medicine
Section of Cardiovascular Medicine
333 Cedar Street, P.O. Box 208017, Rm 307-FMP
New Haven, CT 06520-8017

Birth Date: April 18, 1950, New York City, New York

Education:

June 1967 -	Graduated from Public High School
June 1971 -	B.A. Cum Laude, University of Pennsylvania, Philadelphia, PA
June 1975 -	M.D. Cum Laude, Yale University School of Medicine, New Haven, CT

Board Certification:

1978 -	Diplomate of the American Board of Internal Medicine
1983 -	Diplomate of the American Board of Internal Medicine, Subspecialty of Cardiovascular Disease
2000 -	Diplomate of the American Board of Internal Medicine, Subspecialty of Interventional Cardiology

Career:

1975-1976	Internship in Internal Medicine, Yale-New Haven Hospital, New Haven, CT
1976-1978	Residency in Internal Medicine, Yale-New Haven Hospital, New Haven, CT'
1978-1981	Clinical Associate, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD
1981-1982	Clinical Fellow in Cardiology, Yale-New Haven Hospital, New Haven, CT
1982-1987	Assistant Professor of Medicine and Pathology, Yale University, University Director of the Coronary Care Unit, Yale-New Haven Hospital, New Haven, CT Director of the Yale Cardiovascular Pathology Study Unit
1987-1992	Associate Professor of Medicine and Pathology, Yale University, University Director of the Coronary Care Unit, Yale-New Haven Hospital, New Haven, CT Director of the Yale Cardiovascular Pathology Study Unit Associate Director of the Cardiac Catheterization Laboratory, Yale-New Haven Hospital, New Haven, CT

1992-present	Professor of Medicine and Pathology, Yale University, University Director of the Coronary Care Unit, Yale-New Haven Hospital, New Haven, CT Associate Director of the Cardiac Catheterization Laboratory, Yale-New Haven Hospital, New Haven, CT
1994-present	Associate Section Chief of Cardiovascular Medicine Chief of Clinical Cardiology Services, Yale-New Haven Hospital
1999-2005	Associate Director Yale-New Haven Heart Center
2005-present	Associate Chief, Yale-New Haven Heart and Vascular Center Clinical Chief, Section of Cardiovascular Medicine Yale University School of Medicine
2004–2009	Associate Chairman of Medicine for Clinical Affairs, Department of Internal Medicine, Yale University School of Medicine

Medical Licensure: Connecticut, 1977-present

Military Service: U.S. Public Health Service, July 1, 1978 - October 31, 1981

Honors: Phi Beta Kappa - Elected in 1975
Samuel Kushlan Award - 1977

Department of Internal Medicine
Yale University School of Medicine
Housestaff Teacher of the Year Award 1984-1985

New York's Best Doctors, June 2007
New York's Best Doctors, June 2008

Professional Societies: Fellow - American College of Cardiology
Member, American Medical Association

Summary of Qualifications

- Over 29 years as a critical care nurse with 9 years as direct caregiver ICU nurse, 15 years spent as a Patient Services Manager and 6 years as Director of Patient Services
- Experienced executive leader responsible for over 15 diverse cost centers.
- Accomplished leader responsible for over 500 FTEs with annual budgets over $60 million.

Professional Experience

Director Patient Services, Heart and Vascular Center
Yale New Haven Hospital, New Haven Conn.
June 2008- Present

- Responsible for executive leadership and clinical and financial oversight of 15 diverse cost centers. Areas include two ICUs, cardiac and cardiothoracic; two stepdown units, cardiac medicine and cardio-vascular; one cardiac telemetry unit; one 26 bed observation unit; five cardiac cath labs and three electrophysiology labs; six vascular and neuro interventional labs; nuclear cardiology areas; cardiac exercise lab; ECHO labs; HVC recovery area ,PICC service; HVC procedural nursing and Yale Cardiology practice at Shoreline and Branford.

- Accountable for attaining high performance in all elements of four business pillars: Quality/ safety, Provider of Choice; Employer of Choice; Financial

Director Patient Services, Medicine
Yale New Haven Hospital, New Haven Conn.
September 2006- June 2008

- Responsible for executive leadership and clinical and financial oversight of 13 cost centers. Areas include one cardiac ICU, two medical ICUs, one cardiac telemetry floor, one cardiac stepdown floor, one pulmonary stepdown floor, 5 general medicine floors, PICC Service, ICU resource unit and diagnostic radiology / cardiac nursing.
- Accountable for attaining high performance in all elements of four business pillars: Quality/ safety, Provider of Choice; Employer of Choice; Financial

Patient Services Manager of PICC Service
Yale New Haven Hospital, New Haven Conn.

June 1999- September 2006

- Created bedside PICC insertion service. Service developed to meet both adult and pediatric patient population needs. Coverage provided 7 days; operating 12 hour days Monday-Friday, and 4 hours on-call weekends and holidays.
- Responsible for consulting on approximately 2400 cases a year.

Patient Services Manager of DI Recovery Area
Yale New Haven Hospital, New Haven, Conn.
December 1998-September 2006

- Oversaw site location and creation of 13 bed outpatient recovery area for Diagnostic Imaging and Heart Center procedural patients.
- Patient population includes cardiac cath, EPS, and cardiac biopsy patients.
- Interventional radiology population includes oncology, renal, and vascular.
- Neuro interventional patients are also cared for in this setting.

Patient Services Manager of Diagnostic Imaging
Yale New Haven Hospital, New Haven, Conn.
May 1995-September 2006

- 24 hour accountability for nursing practice and nursing staff in Diagnostic Imaging
- Patient populations include inpatients and outpatients of varying acuity levels and with multiple diagnoses.
- General nursing oversight of 10 principal interventional labs, including 4 cardiac cath labs, 5 peripheral vascular/ neuro interventional labs, 1 electrophysiology lab.
- Primary nursing coverage for 5 MRI scanners with flexible staffing provided for CT biopsies, bronchoscopies, ultrasound, and x-ray.
- Accountable for personnel management, staffing, scheduling, clinical practice, fiscal planning, quality improvement, environmental management, education, orientation, and patient satisfaction.

Patient Services Manager Cardiac ICU
Yale New Haven Hospital, New Haven, Conn.
July 1991-September 2006

- 24 hour responsibility for the clinical, fiscal, and environmental management of a 14 bed cardiac intensive care unit.
- Patient population includes patients with medical diagnosis of cardiogenic shock; end stage cardiomyopathy; acute coronary syndrome; as well as patients with unstable cardiac arrhythmias.
- Accountable for interviewing, selecting, and professional development of approximately 90 staff.

Staff Nurse Cardiac ICU
Yale New Haven Hospital, New Haven, Conn.
July 1982-1991

- Primary nurse responsible for coordinating and implementing care of critically ill patients.
- Preceptor Coordinator
- One of first Clinical Nurse IV recognitions and advancements.

Recent Committee Memberships

- EPIC ancillary committee : Cardiovascular Work group
- Administrative liaison PCA steering committee
- Co-chair BSI steering committee
- Chest Pain Center Steering committee
- HVC Quality / Safety Committee
- D2B steering committee
- Hospital Patient Safety Committee (PSQC)
- SCM steering committee
- Co-Chair Patient Hourly Rounding Steering Committee
- Chair HVC newsletter committee
- Westerly Hospital Cardiac oversight committee
- Women's Heart Program steering committee
- Administrative liaison Cardiac Cluster
- ICU Leadership Group
- Magnet steering Committee
- Nursing Operations Group
- Nursing Cabinet

Recent Special Projects

- Opened 14 bed Observation Unit 5/2011
- Successful Oversight of Chest Pain Center accreditation process
- Successful Oversight of TJC VAD Destination Therapy Accreditation
- Project lead on Telemetry project
- One of several authors on ST-Map ECG software research poster/ article
- CON process, design and opening of 5th Cardiac Cath Lab and 3rd EP Lab
- Replacement and implementation of new EKG Tracemaster View System
- Co-lead development and implementation PCA career ladder
- Opened 9 bed Cardiac / Medicine Step Down Unit 1/2008

- CON process, design and opening of second EPS lab
- Cardiac Nuclear design , construction and relocationto 2EP .
- CON process, design, and opening of two Interventional labs
- CON process design, opening of Neuro Interventional lab
- Design and replacement of Cardiac Swing Lab
- Design and creation of third EPS lab
- Provided operations support for shared services model of Guilford / Branford programs

Professional Organizations/ Certifications

- 1987-present Critical Care Nurse (CCRN)
- 2004-present Certified Nurse Executive (NE-BC)
- 1985- present American Association of Critical Care Nurses (AACN)
- 1992- present American Association of Critical Care Nurses/ South Central Connecticut Chapter (AACN / SCCC)
- American Heart Association – Council of Cardiovascular Nursing
- 2006 –present American Organization Nurse Executives (AONE)
- 2006-present Organization of Nurse Executives, Conn. Chapter (ONE-CT)

Education

- 2002 Quinnipiac University, Hamden, Conn.
  Masters in Health Administration with Distinction
- 1997 Quinnipiac University, Hamden, Conn.
  Bachelors of Science in Nursing, Magna cum Laude
- 1982 Quinnipiac University, Hamden, Conn.
  Associate Degree in Nursing, Cum Laude

Inclusion Summary

Quarters included in this report:

Timeframe	Benchmark Inclusion Status	Submission Type	Included in Executive Summary
2010Q3	G	All Patients	Yes
2010Q4	G	All Patients	Yes
2011Q1	Y	All Patients	No
2011Q2	G	All Patients	Yes

Comparison group included in this report:

Volume Groups	Number of PCI Procedures per R4Q	Number of Hospitals per Volume Group	Your Hospital's Volume Group	Your Annualized PCI Procedure Volume	Your Declared Procedure Volume
1	0-10	51			
2	11-200	274	X	38	40
3	201-400	299			
4	401-600	233			
5	601-1000	255			
6	1001-2000	139			
7	2001+	23			

Release Notes:

CathPCI Outcomes Registry® Report Release notes for 2011Q2

Report Modifications:

1. This is the first release of the Version 4.4 Outcomes Report.
2. In the Executive Summary Footnote there is a change in the text in regard to bleeding. It now reads, 'To qualify, the event must be associated with a hemoglobin drop of >= 3g/dl...' Where the '>=' symbol is the change.
3. We have now added indicators so that a site can see what lines Leapfrog is looking for in our report. Please see the 'Frequently used terminology' section that follows for information about those changes. We did not specify line numbers as those can change, so we put the acronym '(LFHS)' in the report line description to identify those lines that the Leapfrog Hospital Survey wishes for the sites to report to them.

Publish Date: Oct 19, 2011

Frequently used terminology:

R4Q (Rolling Four Quarters)	The four (4) consecutive quarters included in this report. (Example: The 2011Q1 report includes 2010Q2, 2010Q3, 2010Q4 and 2011Q1. The "Q" in 'R4Q" indicates the last quarter of the rolling four quarters).
Benchmark Inclusion Status	Indicates whether a submission will be included in the R4Q aggregated data (benchmark) and comparison group statistics. "Green," "Yellow" and "Red" stoplights denote the status. A "Green" status indicates the submission (one quarter/timeframe) is included in the benchmark and comparison group statistics. The data has successfully passed all data assessment and completeness checks. A "Yellow" status indicates the submission (one quarter/timeframe) is not included in the benchmark and comparison group statistics. Data is displayed in the quarterly column, but is not included in the "My Hospital R4Q" summary. The data has not passed the overall completeness assessment checks. A "Red" status indicates the submission (one quarter/timeframe) is not included in the benchmark or comparison group statistics. Data is not displayed in the quarterly column. A null or blank status indicates no submission has been received for that quarter/timeframe. Data is not displayed in the quarterly column.
Submission Type	Indicates the Submission Type based on the percentage of procedures performed in the submission file. A file with fewer than 50% of the procedures performed indicated as Diagnostic Catheterizations are designated as "PCI Only" submissions.
My Hospital R4Q	The values for a metric/measure (over R4Q) of data submitted by your facility with a Benchmark Inclusion Status of "Green".
All Hospital 50th Pctl	The median (or midpoint or 50th percentile) of all participant aggregated data for the metric or measure. Half of all participants will be above the median, and half will be below. This value will correspond to the midpoint of the box/whisker plot.
All Hospital 90th Pctl	The 90th percentile of all participant aggregated data for the metric or measure. 10% of all participants will be above the 90th percentile value, and 90% will be below. This value will correspond to the right-most endpoint of the box/whisker plot.
Annualized Volume	Annualized Volume is the total number of PCI procedures submitted over the R4Q period, adjusted for the number of quarters in which valid submissions were received during the R4Q period.
Volume Group Pts R4Q	The aggregated value for the metric/measure across all patients in the specified comparison group (over R4Q). Comparison Groups are based on annualized procedure volume. See the Comparison Group chart on the Inclusion Summary page of this report. To be included, data must have a Benchmark Inclusion Status of "Green".
All Registry Pts R4Q	The aggregated value for the measure/metric across all patients (over R4Q). To be included, data must have a Benchmark Inclusion Status of "Green". Only facilities in the United States and outlying territories are included.
Declared Procedure Volume	Indicates the estimated annual procedure volume as reported by the facility on the NCDR website Site Profile.
LFHS	This stands for Leapfrog Hospital Survey. This is to help identify the lines that are used for Leapfrog reporting for our participants. Please note that in the detail lines you will see "(LFHS)" to denote the lines that are to be used for Actual and Risk Adjusted Mortality Rate calculations.
Actual Mortality Rate (LFHS)	Enter your hospital's (actual) observed mortality rate (OMR) as a percentage. Using data from the My Hospital R4Q "Num" column in the current NCDR CathPCI Registry Institutional Outcomes Reports, OMR must be calculated by dividing the number for "Observed Mortality (among eligible) (LFHS)" by the number for "Eligible pts (LFHS)" to obtain the % rate for the most recent rolling four quarters where 12 consecutive months of data was submitted [i.e., Observed Mortality (among eligible) (LFHS)/Eligible pts (LFHS)].
Expected Mortality Rate (LFHS)	Enter your hospital's expected mortality rate (EMR) as a percentage. Using data from the Hospital R4Q "Num" column in the current NCDR CathPCI Registry Institutional Outcomes Reports, EMR must be calculated by dividing the number for "Expected Mortality (among eligible) (LFHS)" by the number for "Eligible pts (LFHS)" to obtain the % rate for the most recent rolling four quarters where 12 consecutive months of data was submitted [i.e., Expected Mortality (among eligible) (LFHS)/Eligible pts (LFHS)].

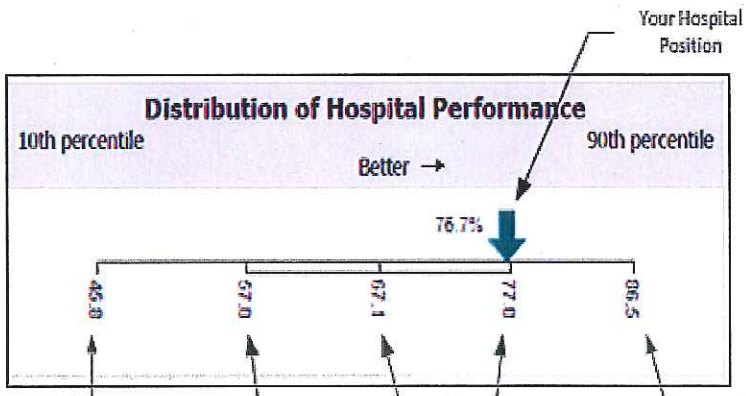
Box and Whisker Plots

Interpreting Box and Whisker Plots



10th percentile
If your hospital scores below the 10th percentile, the arrow will be on the left of this number.

25th Percentile

Median

75th Percentile

90th Percentile
If your hospital scores above the 90th percentile, the arrow will be on the right of this number.

10th Percentile
90% of the hospitals achieved "better" scores than the 10th percentile.

25th Percentile or 1st Quartile
75% of the hospitals achieved "better" scores than the 25th percentile.

50th Percentile or 2nd Quartile
Middle of the distribution: Half of the hospitals data is above and half are below the median.

75th Percentile or 3rd Quartile
25% of the hospitals achieved "better" scores than the 75th percentile.

90th Percentile
10% of the hospitals achieved "better" scores than the 90th percentile.

Executive Summary

CathPCI Registry®

Greenwich Hospital(187346) compared to Rolling Four Quarters (R4Q) for All Hospitals ending 2011Q2

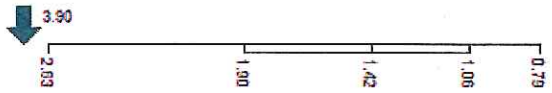
Section I: PCI Performance Measures

Endorsed by the National Quality Forum and appropriate for public reporting

PCI Performance Measures	Distribution of Hospital Performance (10th percentile — 90th percentile; Better →)
1 **PCI in-hospital risk adjusted mortality (all patients)**	

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
3.90	1.42	0.79

Your hospital's PCI in-hospital risk adjusted mortality rate for all patients adjusted using the NCDR® risk adjustment model. [Detail Line:1997]



Note

In-hospital risk adjusted mortality for PCI is the only performance measure in the CathPCI Registry® that has been endorsed by the National Quality Forum. Such performance measures meeting the requirement for approval are intended not only for clinical quality improvement, but also may be considered for purposes of public reporting.

The "Registry Metrics" on the subsequent pages of this report are those measures that have been developed to support self assessment and quality improvement at the provider, hospital, and/or health care system level. While these metrics have not been formally developed by the American College of Cardiology/American Heart Association Task Force for Performance Measures Task Force, they may be identified as evolving measures worthy of consideration for further development into performance measures.

Executive Summary

CathPCI Registry®

Greenwich Hospital(187346) compared to Rolling Four Quarters (R4Q) for All Hospitals ending 2011Q2

Section II: Quality Metrics – to support self assessment and quality improvement at the provider, hospital, and/or health care system level.

	PCI Process Metrics	Distribution of Hospital Performance (10th percentile — 90th percentile; Better →)
2	**Proportion of elective PCIs with prior positive stress or imaging study** My Hospital: — | All Hospitals 50th Pctl: 59.9% | All Hospitals 90th Pctl: 79.8% Proportion of elective PCI procedures (excluding patients with ACS) with an antecedent stress or imaging study with a positive result (suggestive of ischemia) or with a fractional flow reserve value of <=0.8 during the PCI procedure [Detail Line:1511]	3	**Median time to immediate PCI for STEMI patients (in minutes)** My Hospital: 67.0 | All Hospitals 50th Pctl: 63.1 | All Hospitals 90th Pctl: 50.4 Your hospital's median time from hospital arrival to immediate PCI for STEMI patients in minutes. Exclusions: Patients transferred in from another acute care facility; Reasons for delay does not equal none. [Detail Line:1500]	4	**Proportion of STEMI patients receiving immediate PCI w/in 90"** My Hospital: 100.0% | All Hospitals 50th Pctl: 91.4% | All Hospitals 90th Pctl: 100.0% Proportion of STEMI patients with a time from your hospital arrival (or subsequent ECG if ST elevation first noted on subsequent ECG) to immediate PCI <=90". Exclusions: Patients transferred in from another acute care facility; Reasons for delay does not equal none. [Detail Line:1501]	
5	**Median time from ED arrival at STEMI transferring facility to ED arrival at STEMI receiving facility among transferred patients.** My Hospital: — | All Hospitals 50th Pctl: 85.5 | All Hospitals 90th Pctl: 57.8 Your hospital's median time from arrival at transferring facility to ED arrival at STEMI receiving facility among transferred patients. [Detail Line:1503]	
6	**Median time from ED arrival at STEMI transferring facility to immediate PCI at STEMI receiving facility among transferred patients (in minutes)** My Hospital: — | All Hospitals 50th Pctl: 117.8 | All Hospitals 90th Pctl: 83.7 Your hospital's median time from arrival at referring facility to immediate PCI at STEMI receiving facility among transferred patients. Exclusions: Reasons for delay does not equal none. [Detail Line:1504]	7	**Median fluoro time (in minutes)** My Hospital: 9.5 | All Hospitals 50th Pctl: 9.1 | All Hospitals 90th Pctl: 6.6 Inclusion criteria: PCI of one vessel/lesion. Exclusion criteria: Prior CABG, or "other" procedure during the same lab visit; PCI of >1 vessel/lesion. [Detail Line:1629]	8	**Proportion of patients with aspirin prescribed at discharge** My Hospital: — | All Hospitals 50th Pctl: 98.2% | All Hospitals 90th Pctl: 100.0% Proportion of patients (without a documented contraindication) with aspirin prescribed at discharge. [Detail Line:1959]	9	**Proportion of patients with thienopyridine prescribed at discharge** My Hospital: — | All Hospitals 50th Pctl: 99.1% | All Hospitals 90th Pctl: 100.0% Proportion of patients (without a documented contraindication) with a stent implanted that had a thienopyridine prescribed at discharge. [Detail Line: 1968]

Executive Summary

CathPCI Registry®

Greenwich Hospital(187346) compared to Rolling Four Quarters (R4Q) for All Hospitals ending 2011Q2

Section II: Quality Metrics – to support self assessment and quality improvement at the provider, hospital, and/or health care system level.

10 **Statins prescribed at discharge**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
100.0%	91.5%	97.3%

Proportion of patients (without a documented contraindication) prescribed a statin at discharge. [Detail Line:1964]

PCI Outcome Metrics

Distribution of Hospital Performance

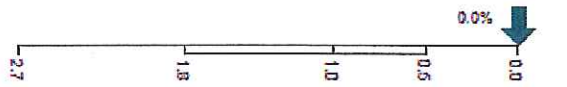
10th percentile — 90th percentile

Better →

11 **Proportion of PCI procedures with vascular access site injury requiring treatment or major bleeding***

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
0.0%	1.0%	0.0%

Your hospital's proportion of patients (excluding CABG or other surgery during same admission) with major access site related injury requiring treatment or major bleeding. [Detail Line:1836]



12 **Proportion of PCI patients with emergency CABG**

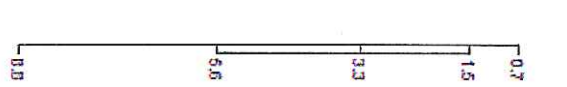
My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
0.0%	0.1%	0.0%

Your hospital's proportion of patients having emergency CABG (at your facility or transferred to another facility). [Detail Line:1941]

13 **Proportion of PCI procedures with a post procedure MI (among hospitals routinely collecting post-PCI biomarkers)****

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
	3.3%	0.7%

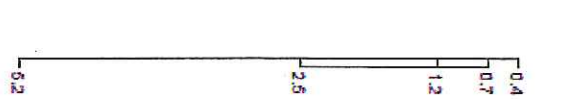
Your hospital's proportion of biomarker positive, post procedure myocardial infarction. Inclusions: Submissions with >= 90% of pts with biomarkers coded; LOS>=1; Elective patients [Detail Line:1799]



14 **Proportion of PCI procedures with post procedure MI (among hospitals who do not routinely collect post-PCI biomarkers)****

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
	1.2%	0.4%

Your hospital's proportion of biomarker positive, post procedure myocardial infarction. Inclusions: Submissions with < 90% of pts with biomarkers coded; LOS>=1; Elective patients [Detail Line:1800]



15 **Proportion of PCI procedures with acute kidney injury*****

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
	2.2%	1.0%

Your hospital's proportion of patients who had a rise of serum creatinine of > 50% over the pre-procedure baseline (excluding patients on dialysis pre-procedure). Inclusions: >= 90% of patients with a pre and post creatinine coded; LOS >=1 day. [Detail Line:1933]

16 **Proportion of PCI procedures with post procedure stroke**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
0.0%	0.0%	0.0%

Your hospital's proportion of patients with stroke post procedure. [Detail Line:1807]

17 **Composite: Proportion of PCI patients with death, emergency CABG, stroke or repeat target vessel revascularization.**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
6.9%	2.3%	0.9%

Your hospital's proportion of patients with death, emergency CABG, stroke or repeat target vessel revascularization post procedure up to hospital discharge. Excludes patients with stroke and an elective, urgent or salvage CABG during same admission. [Detail Line:1797]

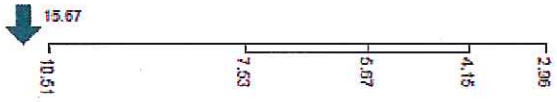
18 **PCI in-hospital risk adjusted mortality (patients with STEMI)**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
15.67	5.67	2.96

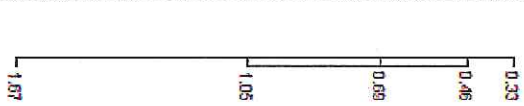
Your hospital's PCI in-hospital risk adjusted mortality rate for patients with STEMI adjusted using the NCDR® risk adjustment model. [Detail Line:2006]



19 **PCI in-hospital risk adjusted mortality (STEMI patients excluded)**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
	0.69	0.33

Your hospital's PCI in-hospital risk adjusted mortality rate for patients with other diagnoses (not STEMI) using the NCDR® risk adjustment model. [Detail Line:2015]



Diagnostic Cath Process Metrics

Distribution of Hospital Performance

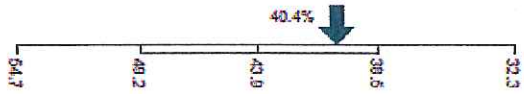
10th percentile — 90th percentile

Better →

20 **Incidence of non-obstructive CAD (elective patients only)**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
40.4%	43.9%	32.3%

Patients with an elective diagnostic cath and coronary angiography with all native coronary territories <50% Exclusions: Patients with prior CABG, cardiac transplant evaluation; pre-op evaluation for non-cardiac surgery and diagnostic cath treatment recommendation of "other cardiac therapy without CABG or PCI". [Detail Line:1252]



Diagnostic Cath Outcomes Metrics

Distribution of Hospital Performance

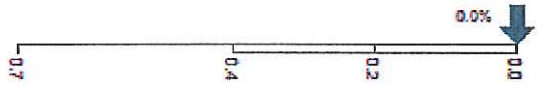
10th percentile — 90th percentile

Better →

21 **Proportion of Diagnostic Catheterization procedures with vascular access site injury requiring treatment or major bleeding***

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
0.0%	0.2%	0.0%

Your hospital's proportion of patients with major access site related injury requiring treatment or major bleeding. [Detail Line:1301]



Utilization Metrics

Distribution of Hospital Performance

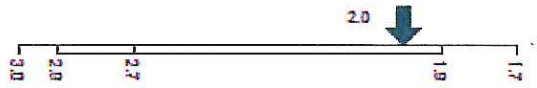
10th percentile — 90th percentile

Better →

22 **Median post-procedure length of stay (in days) for PCI patients with STEMI**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
2.0	2.7	1.7

Your hospital's median post-procedure length of stay (in days) for PCI patients with STEMI. [Detail Line:2071]



Data Quality Metrics

Distribution of Hospital Performance

10th percentile — 90th percentile

Better →

24 **Proportion of PCI procedures with creatinine assessed pre and post PCI**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
79.3%	86.0%	96.1%

Proportion of PCI patients with creatinine assessed pre and post procedure. Inclusions: LOS >=1 day. [Detail Line:1932]

36 **Patients WITHOUT Acute Coronary Syndrome (Test Metric): Proportion of evaluated PCI procedures that were inappropriate**

My Hospital	All Hospitals 50th Pctl	All Hospitals 90th Pctl
	9.5%	0.0%

Proportion of PCI procedures that were evaluated as "Inappropriate", among patients without ACS, meaning coronary revascularization is not generally acceptable and is not a reasonable approach for the indication and is unlikely to improve the patients' health outcomes or survival. [Detail Line:1585]

Executive Summary Footnotes

*Vascular access site injury requiring treatment or major bleeding is defined as:

1.Bleeding at access site, hematoma at access site, or retroperitoneal bleed that occur within 72 hours of the procedure. To qualify, the event must be associated with a hemoglobin drop of >= 3 g/dL; transfusion of whole or packed red blood cells, or a procedural intervention/surgery at the bleeding site to reverse/stop or correct the bleeding. This excludes "GI", "GU" and "Other" bleeds.

2.Major access site related injury requiring treatment includes access site occlusion, peripheral embolization, dissection, pseudoaneurysm, AV fistula requiring treatment anytime from the procedure until discharge.

**Your rate of post procedure MI cannot be reported if you only collected cardiac biomarkers on <90% of your patients who were in the hospital >=1 day.

***Your rate of acute kidney injury cannot be reported if you only collected creatinine pre and post procedure on <90% of your patients who were in the hospital >=1 day.

ATTACHMENT XII

Greenwich Hospital's Letter of Intent to the Office of Health Care Access dated March 9, 2011 (PAMI Outcomes Limitations)

GREENWICH HOSPITAL
YALE NEW HAVEN HEALTH

March 9, 2011

Kimberly Martone
Director of Operations
Office of Health Care Access
State of Connecticut Department of Public Health
410 Capitol Avenue, MS#13HCA
P.O. Box 340308
Hartford, CT 06134-0308

Re: Docket Number 03-30148-CON, as modified by Docket Number 06-30148-MDF, Docket Number 08-30148-MDF and Docket Number 09-30148-MDF (Establishment of a Primary Interventional Cardiac Service at Greenwich Hospital)

Dear Ms. Martone:

This letter is in follow up to a phone conversation that we had earlier this year with staff of the Office of Health Care Access ("OHCA") regarding the reporting obligations of Greenwich Hospital under the above-referenced docket. Pursuant to Docket Number 09-30148-MDF, in the event that Greenwich Hospital participates in the American College of Cardiology National Cardiovascular Database (the "ACC-NCDR"), it is required to submit to OHCA, on an annual basis, any and all Executive Summary pages from the Institutional Outcomes Reports received from the ACC-NCDR. Greenwich Hospital may, however, determine not to participate in the ACC-NCDR, provided that it so notifies OHCA of its decision.

Greenwich Hospital has, since September of 2008, participated in the ACC-NCDR and has made various submissions to OHCA in compliance with Docket Number 09-30148-MDF. ACC-NCDR has, however, recently modified its database criteria to require reporting on additional measures, many of which apply to programs that provide for both primary and elective angioplasty services. In addition, the ACC-NCDR reports provide comparative benchmarking for all participating programs, and do not separately benchmark programs that provide only primary/emergency angioplasty (so-called "PAMI only programs") such as that in operation at Greenwich Hospital. As a result, the report shows an "apples to oranges" comparison of data and is not a good indication of performance for PAMI only programs such as Greenwich Hospital's program.

As a result, Greenwich Hospital's performance is benchmarked against programs that have significantly higher volumes that include elective angioplasty cases. This results in benchmarking that is skewed, can be incorrectly interpreted, and limits valid comparisons. However, at this time the ACC-NCDR data appears to be the only benchmarking data set available to hospitals. The ACC-NCDR data is not designed to be used in the public domain but rather is designed to be used as an internal document for benchmarking purposes by hospitals. The public may not be aware of the data discrepancies outlined above and, therefore, not be able to correctly either interpret the data or draw correct conclusions about a hospital's performance based on the data. Upon Greenwich Hospital's submission of the ACC-NCDR data to the Office of Health Care Access, the data becomes available to the public under Freedom of Information laws where it may be incorrectly interpreted as discussed above.

Enclosed are the Greenwich Hospital ACC-NCDR Executive Summary pages for the period from July 1, 2009 through June 30, 2010 in compliance with its obligations under Docket Number 09-30148-MDF.

<u>In light of the concerns about the data and results obtained from ACC-NCDR, Greenwich Hospital respectfully requests that the Executive Summary be qualified by the information contained in this letter and that any disclosure or other use of the Executive Summary or the data contained therein be accompanied by a copy of this letter.</u>

Thank you for your consideration. Please feel free to contact me at (203) 863-3909 should you have any questions.

Sincerely,

Nancy M. Hamson

Nancy M. Hamson
Planning Director

Executive Summary

CathPCI Registry®

Greenwich Hospital(187346) compared to Rolling Four Quarters (R4Q) for All Hospitals ending 2010Q2

Section I: PCI Performance Measures

Endorsed by the National Quality Forum and appropriate for public reporting

PCI Performance Measures

Distribution of Data

10th percentile — Better → — 90th percentile

1 **PCI in-hospital risk adjusted mortality (all patients)**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
2.54		1.42	0.77

Your hospital's PCI in-hospital risk adjusted mortality rate for all patients adjusted using the NCDR® risk adjustment model. [Detail Line:1979]

Note

In-hospital risk adjusted mortality for PCI is the only performance measure in the CathPCI Registry® that has been endorsed by the National Quality Forum. Such performance measures meeting the requirement for approval are intended not only for clinical quality improvement, but also may be considered for purposes of public reporting.

The "Registry Metrics" on the subsequent pages of this report are those measures that have been developed to support self assessment and quality improvement at the provider, hospital, and/or health care system level. While these metrics have not been formally developed by the American College of Cardiology/American Heart Association Task Force for Performance Measures Task Force, they may be identified as evolving measures worthy of consideration for further development into performance measures.

Any disclosure of this data should be accompanied by the Greenwich Hospital cover letter dated March 9, 2011

Executive Summary

CathPCI Registry®

Greenwich Hospital(187346) compared to Rolling Four Quarters (R4Q) for All Hospitals ending 2010Q2

Section II: Quality Metrics – to support self assessment and quality improvement at the provider, hospital, and/or health care system level.

PCI Process Metrics

Distribution of Data

10th percentile · Better → · 90th percentile

2 **Positive stress or imaging study prior to elective PCI**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
	50.5%	52.4%	70.9%

Proportion of elective PCI procedures (excluding patients with ACS) with an antecedent stress or imaging study with a positive result (suggestive of ischemia) or with a fractional flow reserve assessed during the procedure. [Detail Line:1515]

3 **Median time to immediate PCI for STEMI patients (in minutes)**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
76.5	67.0	64.0	52.1

Your hospital's median time from hospital arrival to immediate PCI for STEMI patients in minutes. Exclusions: Patients transferred in from another acute care facility; Reasons for delay does not equal none. [Detail Line:1504]

4 **Proportion of STEMI patients receiving immediate PCI w/in 90"**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
88.5%	87.2%	87.9%	98.4%

Proportion of STEMI patients with a time from your hospital arrival (or subsequent ECG if ST elevation first noted on subsequent ECG) to immediate PCI <=90". Exclusions: Patients transferred in from another acute care facility; Reasons for delay does not equal none. [Detail Line:1505]

5 **Median time from ED arrival at STEMI transferring facility to ED arrival at STEMI receiving facility among transferred patients.**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
	76.0	86.0	57.5

Your hospital's median time from arrival at transferring facility to ED arrival at STEMI receiving facility among transferred patients. [Detail Line:1507]

6 **Median time from ED arrival at STEMI transferring facility to immediate PCI at STEMI receiving facility among transferred patients (in minutes)**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
	109.0	118.0	84.9

Your hospital's median time from arrival at referring facility to immediate PCI at STEMI receiving facility among transferred patients. Exclusions: Reasons for delay does not equal none. [Detail Line:1508]

7 **Median fluoro time (in minutes)**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
12.1	9.6	8.8	6.5

Inclusion criteria: PCI of one vessel/lesion. Exclusion criteria: Prior CABG, or "other" procedure during the same lab visit; PCI of >1 vessel/lesion. [Detail Line:1612]

8 **Aspirin prescribed at discharge**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
100.0%	95.3%	97.0%	99.8%

Proportion of patients (without a documented contraindication) with aspirin prescribed at discharge. [Detail Line:1941]

9 **Thienopyridine prescribed at discharge (patients with stents)**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
100.0%	97.3%	98.1%	100.0%

Proportion of patients (without a documented contraindication) with a stent implanted that had a thienopyridine prescribed at discharge. [Detail Line: 1950]

CathPCI Registry®

Greenwich Hospital(187346) compared to Rolling Four Quarters (R4Q) for All Hospitals ending 2010Q2

Section II: Quality Metrics – to support self assessment and quality improvement at the provider, hospital, and/or health care system level.

10 **Lipid lowering agent prescribed at discharge (pts with dyslipidemia)**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
80.0%	90.8%	92.4%	98.0%

Proportion of patients (without a documented contraindication) prescribed a lipid lowering agent at discharge.
Inclusions: History of dyslipidemia [Detail Line:1948]

PCI Outcome Metrics — **Distribution of Data** (10th percentile … 90th percentile; better →)

11 **Vascular access site injury requiring treatment or major bleeding***

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
0.0%	1.9%	1.4%	0.0%

Your hospital's proportion of patients (excluding CABG or other surgery during same admission) with major access site related injury requiring treatment or major bleeding. [Detail Line:1818]

12 **Emergency CABG**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
0.0%	0.5%	0.3%	0.0%

Your hospital's proportion of patients having emergency CABG (at your facility or transferred to another facility). [Detail Line:1923]

13 **Post procedure MI (among hospitals routinely collecting post-PCI biomarkers)****

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
	3.2%	3.0%	0.7%

Your hospital's proportion of biomarker positive, post procedure myocardial infarction. Inclusions: Submissions with >= 90% of pts with biomarkers coded; LOS>=1; Elective patients [Detail Line:1781]

14 **Post procedure MI (among hospitals who do not routinely collect post-PCI biomarkers)****

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
	2.0%	1.4%	0.4%

Your hospital's proportion of biomarker positive, post procedure myocardial infarction. Inclusions: Submissions with < 90% of pts with biomarkers coded; LOS>=1; Elective patients [Detail Line:1782]

15 **Acute kidney injury*****

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
3.6%	1.9%	2.2%	0.9%

Your hospital's proportion of patients who had a rise of serum creatinine of > 50% over the pre-procedure baseline (excluding patients on dialysis pre-procedure).
Inclusions: >= 90% of patients with a pre and post creatinine coded; LOS >=1 day. [Detail Line:1915]

16 **Post procedure stroke**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
0.0%	0.2%	0.2%	0.0%

Your hospital's proportion of patients with stroke post procedure. [Detail Line:1788]

17 **Composite: Death, emergency CABG, stroke or repeat target vessel revascularization**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
5.7%	2.8%	2.3%	0.8%

Your hospital's proportion of patients with death, emergency CABG, stroke or repeat target vessel revascularization post procedure up to hospital discharge.
Exclusions: Staged PCI during same admission. [Detail Line:1779]

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
0.0%	2.1%	2.0%	0.0%

Proportion of patients who received a transfusion of whole blood or red blood cells after a PCI procedure. Exclusions: Patients having CABG or other major surgery during the same admission. [Detail Line:1820]

26 **Test Data Quality Metric: Biomarkers assessed post-PCI for elective inpatients**

My Hospital	Vol Group R4Q	All Hosp	90th Pctl
	51.8%	45.2%	96.0%

Proportion of elective procedures with biomarkers assessed post PCI. Inclusion criteria: LOS >= 1 day and hospital status is "not outpatient". [Detail Line:1912]

Executive Summary Footnotes

*Vascular access site injury requiring treatment or major bleeding is defined as:

1.Bleeding at access site, hematoma at access site, or retroperitoneal bleed that occur within 72 hours of the procedure. To qualify, the event must be associated with a hemoglobin drop of >3 g/dL; transfusion of whole or packed red blood cells, or a procedural intervention/surgery at the bleeding site to reverse/stop or correct the bleeding. This excludes "GI", "GU" and "Other" bleeds.

2.Major access site related injury requiring treatment includes access site occlusion, peripheral embolization, dissection, pseudoaneurysm, AV fistula requiring treatment anytime from the procedure until discharge.

**Your rate of post procedure MI cannot be reported if you only collected cardiac biomarkers on <90% of your patients who were in the hospital >=1 day.

***Your rate of acute kidney injury cannot be reported if you only collected creatinine pre and post procedure on <90% of your patients who were in the hospital >=1 day.

Dear Sir or Madam:

This is in response to your request of October 4, 2007, regarding your organization's tax-exempt status.

In February 1972 we issued a determination letter that recognized your organization as exempt from federal income tax. Our records indicate that your organization is currently exempt under section 501(c)(3) of the Internal Revenue Code.

Our records indicate that your organization is also classified as a public charity under sections 509(a)(1) and 170(b)(1)(A)(vi) of the Internal Revenue Code.

Our records indicate that contributions to your organization are deductible under section 170 of the Code, and that you are qualified to receive tax deductible bequests, devises, transfers or gifts under section 2055, 2106 or 2522 of the Internal Revenue Code.

If you have any questions, please call us at the telephone number shown in the heading of this letter.

Sincerely,

Michele M. Sullivan

Toll Free Telephone Number: 1-877-829-5500

Dear Taxpayer:

This is in response to your Oct. 21, 2010, request for information regarding your tax-exempt status.

Our records indicate that you were recognized as exempt under section 501(c)(3) of the Internal Revenue Code in a determination letter issued in November 1966.

Our records also indicate that you are not a private foundation within the meaning of section 509(a) of the Code because you are described in section(s) 509(a)(1) and 170(b)(1)(A)(iii).

Donors may deduct contributions to you as provided in section 170 of the Code. Bequests, legacies, devises, transfers, or gifts to you or for your use are deductible for Federal estate and gift tax purposes if they meet the applicable provisions of sections 2055, 2106, and 2522 of the Code.

Please refer to our website www.irs.gov/eo for information regarding filing requirements. Specifically, section 6033(j) of the Code provides that failure to file an annual information return for three consecutive years results in revocation of tax-exempt status as of the filing due date of the third return for organizations required to file.

If you have any questions, please call us at the telephone number shown in the heading of this letter.

Sincerely yours,

Rita A. Leete

Public Notice

Pursuant to section 19a-638 of Connecticut General Statutes, Yale-New Haven Hospital will submit the following Certificate of Need application:

Applicant(s): Yale-New Haven Hospital
Greenwich Hospital
Address: 5 Perryridge Road
Town: Greenwich
Proposal: Establish and Operate an Elective Angioplasty Program at Greenwich Hospital
Estimated Total Project Cost/Expenditure: $0

GREENWICH TIME
CERTIFICATE OF PUBLICATION

I, Sarah Hussey
Being duly sworn, depose and say that I am a Representative in the employ of SOUTHERN CONNECTICUT NEWSPAPERS, INC., Publisher of *The Advocate* and *Greenwich Time*, that a LEGAL NOTICE as stated below was published in the GREENWICH TIME.

Subscribed and sworn to before me on this 7.th Day of December, A.D. 2011.

Pamela E. Caluori

Project Name: Establish and Operate an Elective Angioplasty Program at Greenwich Hospital

Statute Reference: Section 19a-638, C.G.S.

Estimated Total Capital Expenditure: $0

1. Project Description: Establishment of Cardiac Services

Please provide a narrative detailing the proposal.

Greenwich Hospital and Yale-New Haven Hospital, both members of Yale New Haven Health System, propose to build upon the successful Primary Angioplasty program (PAMI) at Greenwich Hospital, which serves as a satellite of the Yale-New Haven Heart and Vascular Center, and which received permanent approval status from the Office of Health Care Access in July 2008 after completion of a three-year demonstration project. This proposal seeks to add elective angioplasty to the other cardiac services provided at Greenwich Hospital as part of the Yale-New Haven Heart and Vascular Center. The addition of elective angioplasty to a community hospital setting represents a national trend in cardiac services that has occurred over the past several years. Certain interventional cardiac services, including elective angioplasty, are no longer exclusively the province of academic medical centers and large teaching hospitals, but are being appropriately expanded to smaller community hospitals with comparable results. The addition of elective angioplasty to Greenwich Hospital's continuum of high quality cardiac services would be in keeping with similar expansions in numerous other states, and would permit the Hospital to more fully utilize and sustain its high quality infrastructure.

Angioplasty is an interventional procedure performed in the cardiac catheterization laboratory that is used to open blocked or narrowed coronary arteries due to coronary heart disease, thereby improving blood flow to the heart. In most cases, it is performed on an elective basis (and called elective angioplasty), although certain patients require a primary (emergency) angioplasty if they are experiencing a certain type of myocardial infarction. In most cases, a stent is placed in the patient's artery during the procedure in order to reduce the likelihood of future blockage in that artery. Elective angioplasty frequently relieves symptoms of coronary heart disease such as angina (chest pain) and shortness of breath. It is a relatively low-risk procedure that does not require general anesthesia and is one of the most common cardiac procedures.

Elective angioplasty services at Greenwich Hospital will complement cardiac services currently provided at the Hospital and will be a part of the integrated Yale-New Haven Heart & Vascular Center supported administratively and clinically by Yale-New Haven Hospital (YNHH). The clinical and operational infrastructure to provide a high quality full-service cardiac program already exists, and will be enhanced by the ability to offer elective angioplasties. Greenwich Hospital is already performing angioplasty on more acutely ill patients through its primary angioplasty program and the staff and physicians are well prepared to perform elective angioplasty for less acute patients. The proposed Greenwich Hospital program will be included in the existing satellite cardiology program of the Yale-New Haven Heart & Vascular Center, and as it does today with the primary angioplasty program, will follow the YNHH clinical safety and quality protocols, credentialing processes and operational policies and procedures. The Medical Director of the cardiac services program at Greenwich Hospital is appointed by the Yale University School of Medicine (YSM) Department of Cardiology and is a member of the YSM's interventional cardiology faculty. In addition, the privileged medical staff is associated with either YSM Department of Cardiology, members of which currently practice at Greenwich Hospital as part of the existing primary angioplasty program or are members

of the Greenwich Hospital medical staff with privileges in performing angioplasties. All associated physicians will utilize the lab in accordance with pre-established clinical protocols and quality standards.

2. **Clear Public Need**

   a. Explain why there is a clear public need for the proposal. Provide evidence that demonstrates this need.

   Approved Docket Number (DN) 08-30148-MDF demonstrated clear public need for emergency angioplasty services at Greenwich Hospital. The current proposal expands upon DN 08-30148-MDF to demonstrate that the same population, from which the Hospital's primary angioplasty patients originate, also have a clear need for access to their provider of choice for high quality elective angioplasty services.

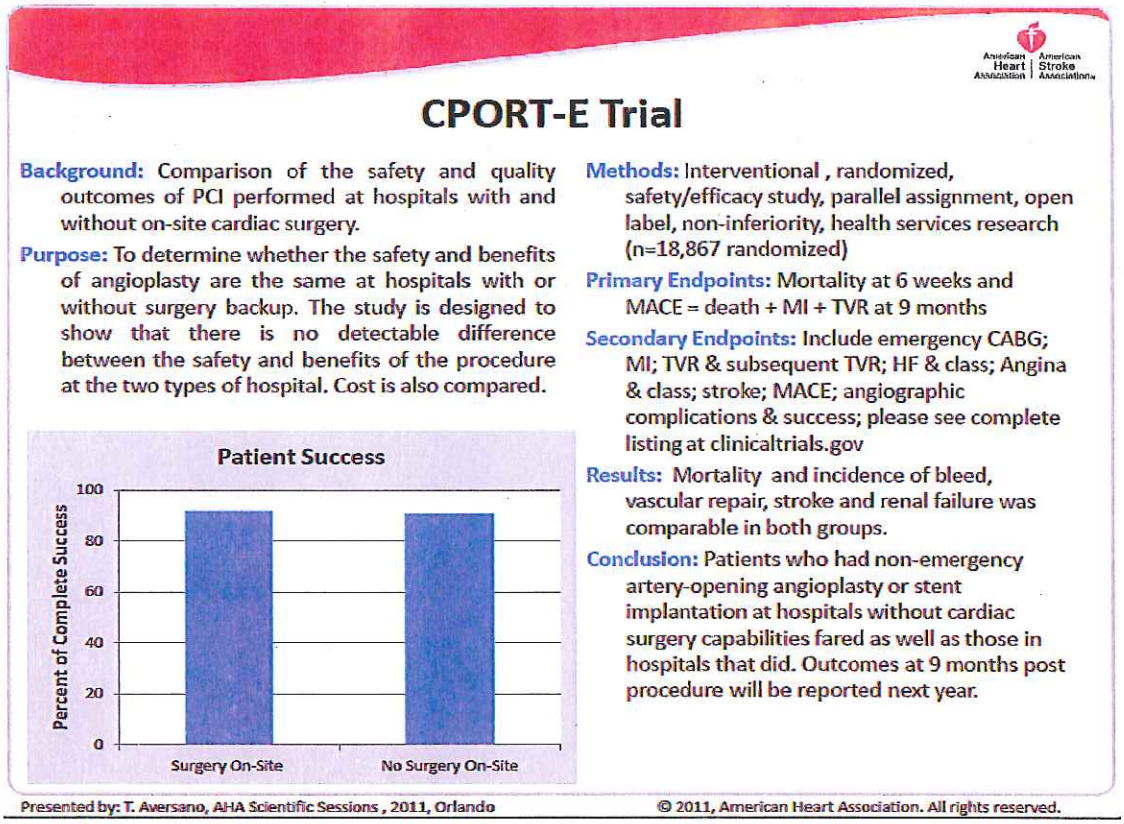
   Clear public need for the proposal is supported by the following three key factors:
   - **Local access to elective angioplasty care at Greenwich Hospital is needed and appropriate:**
   - **Greenwich Hospital must address the cost-effectiveness of angioplasty services; and**
   - **The proposed program will improve the quality of care of elective angioplasty services provided to Greenwich Hospital service area patients.**

   These factors will be described in more detail below.

   <u>Local access to elective angioplasty care at Greenwich Hospital is needed and appropriate</u> as supported by the following three key factors:
   - **Recent clinical guidelines and studies demonstrate the safety and efficacy of elective angioplasty programs without cardiac surgery back-up;**
   - **National and local trends that demonstrate improved access to elective angioplasty; and**
   - **The historical lack of access for elective angioplasty for patients who seek care at Greenwich Hospital.**

   Recent Clinical Guidelines & Studies Demonstrate the Safety and Efficacy of Elective Angioplasty without Cardiac Surgery Back-Up
   The most recent American College of Cardiology/American Heart Association/ Society for Cardiac Angiography and Intervention (ACC/AHA/SCAI) PCI guidelines released on November 7, 2011 represent a significant change in the recommendation level regarding elective angioplasty in hospitals without cardiac surgery programs. The new guidelines assign a class IIB recommendation, which means the benefit is greater than or equal to the risk, for elective angioplasty without cardiac surgery back-up.

Recent studies and publications indicate that standalone elective angioplasty can be safely performed with positive outcomes. The first major study, assessing outcomes of patients undergoing angioplasty at centers with and without surgical back-up, found comparable results at both types of facilities. Preliminary results from the CPORT-E trial led by Dr. Thomas Aversano at Johns Hopkins University were released in mid-November 2011. In this large multi-center study, nearly 14,000 patients were randomly assigned to have elective angioplasty at a hospital with onsite surgical capability, and approximately 4,500 patients were randomly assigned to have elective angioplasty at a hospital without surgical backup. The death rate after six weeks was the same for each group, and neither group of patients was more likely to need emergency cardiac surgery. A summary slide of study results presented in November 2011 at an American Heart Association conference is shown below.



An American Heart Association (AHA) news release summarizing the CPORT-E study's findings, included as Attachment I, stated that "Patients who had non-emergency artery-opening angioplasty or stent implantation at experienced hospitals without on-site heart surgery capabilities fared no worse than those in surgery-equipped hospitals" and also noted the following:

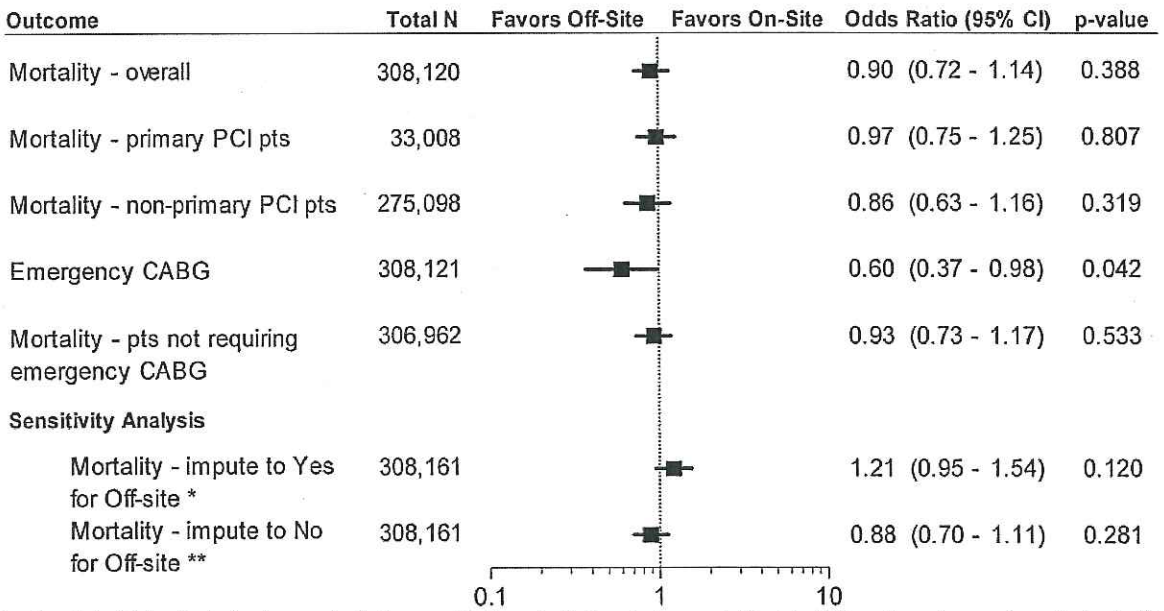
- **Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without heart surgery capabilities fared as well as those in hospitals that did; and**
- **Both groups of patients had less than a 1 percent death rate.**

Interestingly, before results from the CPORT-E study were available, some states (such as New Jersey) that had hospitals participating in the study legislated that these hospitals that had started elective angioplasty programs on the study protocol, could continue their elective angioplasty programs even though the protocol has completed enrollment.

In a separate article, Param Puneet Singh, MD, et al (2011), published '*Outcomes of Nonemergent Percutaneous Coronary Intervention With and Without Onsite Surgical Backup: a Meta Analysis.*' The meta-analysis suggests that there is no difference in outcome with regard to risk of nonfatal myocardial infarction, need for emergency coronary artery bypass grafting, and the risk of death in patients undergoing elective angioplasty in hospitals with and without on-site cardiac surgery backup (see Attachment II).

The National Cardiovascular Data Registry (NCDR, 2009) evaluated the national experience for angioplasty without surgery onsite. The NCDR studied programs that already perform these procedures. Data from 60 hospitals and approximately 8,700 patients who had angioplasty at centers without on-site cardiac surgery ("offsite centers") were compared to 405 hospitals and approximately 300,000 patients at centers with cardiac surgery on-site ("onsite centers"). One notable finding was that after risk adjustment there were no mortality differences between off- and on-site facilities among total angioplasty patients, primary angioplasty patients, non-primary angioplasty patients, or patients who did not require emergency surgery (see chart below). In fact, there were higher risk-adjusted odds of emergency surgery in on-site angioplasty centers.

Risk-Adjusted Analysis of Outcomes



Odds ratio plot of risk-adjusted outcomes, including sensitivity analysis for missing mortality data. Odds ratio: outcomes for patients at off-site (vs. on-site) facilities, adjusting for within site correlations and potential confounding variables. *Worst case scenario: all patients with missing mortality data were considered to have died. **Best case scenario: all patients with missing mortality data were considered as alive. CABG _ coronary artery bypass graft surgery; CI = confidence interval; PCI = percutaneous coronary intervention; pts = patients.

Source: Kutcher, M, et.al, Percutaneous Coronary Interventions in Facilities Without Cardiac Surgery On Site: A Report from the National Cardiovascular Data Registry (NCDR), Journal of the American College of Cardiology, Volume 54, No. 1, June 30, 2009, pgs. 16 - 24

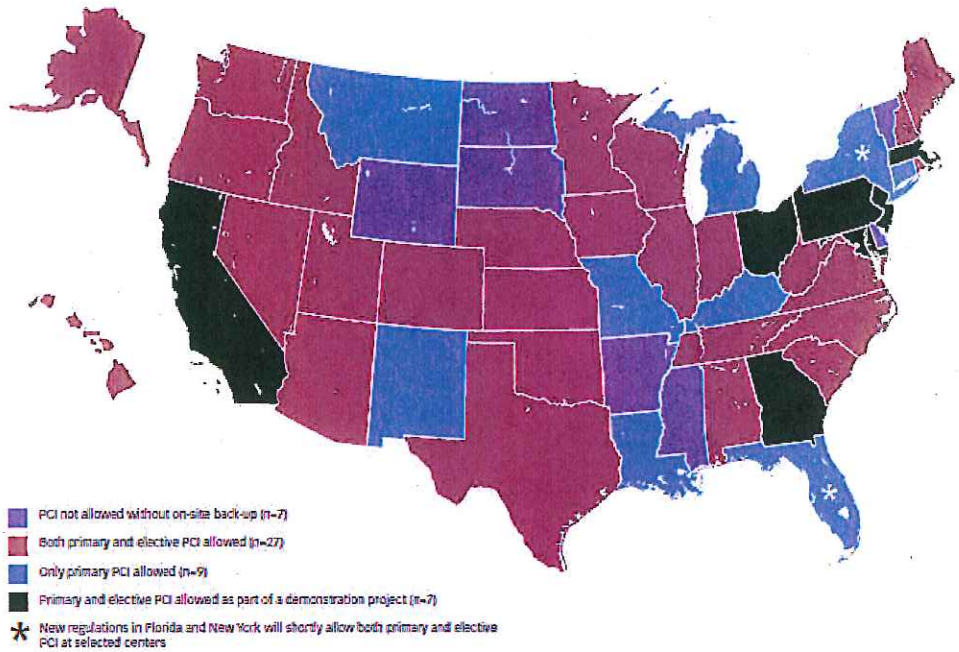
Despite lower annual angioplasty procedural volumes and more patients presenting with myocardial infarction (MI) subsets, off-site angioplasty facilities reporting to the NCDR Cath PCI Registry had similar rates of procedural success, morbidity, emergency surgery, and risk-adjusted mortality when compared with on-site angioplasty centers. Another potentially important observation is that on-site surgery did not necessarily confer an advantage for the rare patient that did require emergent surgery. In cases that required emergency surgery, off-site angioplasty centers had similar observed procedure success, morbidity, emergency cardiac surgery rates and mortality. (See Attachment III)

National and Local Trends Demonstrate Improved Access to Elective Angioplasty

In the past several years, the interventional cardiology field has experienced a significant expansion of services. Health Care Advisory Board research shows that as of 2009, 34 states allowed elective angioplasty to be performed without surgical backup, including New York, Pennsylvania, New Hampshire and Maine; seven of the 34 states allowed it as part of a demonstration project. In New York, ten hospitals have been granted approval to provide elective angioplasty without on-site cardiac surgery, including White Plains Hospital in White Plains. In January 2011, California enacted a six site "pilot" program for elective angioplasty without on-site cardiac surgery.

The map below, by the Health Care Advisory Board, shows the states that allow percutaneous coronary intervention without onsite cardiac surgical back-up as of 2009.

Figure 1: Status of Percutaneous Coronary Intervention without On-site Cardiac Surgical Back-up in the US



There are now only seven states (Arkansas, Delaware, Mississippi, North Dakota, South Dakota, Vermont, and Wyoming) where neither primary nor elective percutaneous coronary intervention (PCI) is allowed without on-site surgery. Legislation is pending in California to allow a carefully monitored demonstration project of elective PCI without on-site back-up. Primary PCI without on-site surgery is allowed in Washington, but not elective PCI. However, Washington has a liberal definition of emergency PCI such that patients with acute coronary syndromes and non-ST segment elevation myocardial infarction who have stabilized are allowed to undergo PCI at facilities without on-site surgery. Florida and New York both have rule changes pending to allow both primary and elective PCI at selected facilities without on-site surgery. Modified from Dehmer et al., 2007.[10]

Source: Dehmer, Gregory, J., Percutaneous Coronary Intervention without On-site Surgical Back-up, US Cardiology, 2009, Vol. 6 (1), pages 69-74

Since this map was published in 2009, both New York and Florida have allowed elective angioplasty without onsite surgical backup, as the footnote indicates.

Significantly, of the 34 states that allow standalone elective angioplasty, 28 require Certificate of Need regulatory approval, including New York. The majority of states permit both primary and elective angioplasty. Based on the new ACC/AHA/SCAI guidelines, the CPORT-E trial results and other recently published studies, one would expect elective angioplasty without cardiac surgery back-up to continue to expand.

An additional indication of the reduced level of risk of elective angioplasty and the routine nature of the procedure is the trend towards performing the procedure on an outpatient basis. This practice occurs throughout the country, including Connecticut. The percentage of inpatient angioplasty in Connecticut has declined each year from 98.9% in FY 2008 to 89.6% in the latest CHIME data from FY 2011.

The Historical Lack of Access for Elective Angioplasty for Patients who Seek Care at Greenwich Hospital

Since Fiscal Year 2008, 272 patients came to Greenwich Hospital and needed elective angioplasty but could not access this service. Limits placed on access to this routine cardiac procedure required these patients to be transferred to another facility, in some cases outside Connecticut. Due to existing physician referral patterns, the majority of these 246 patients were transferred to Yale-New Haven Hospital, as shown in the table below. An additional 26 patients were discharged and referred for elective angioplasty at a future time.

Number of Patients Discharged Directly from GH to Another Institution for Elective Angioplasty

Fiscal Year	Yale-New Haven Hospital	Westchester Medical Center	Cornell	Columbia	Stamford	West Haven VA	Total Transfers	Number of Patients Discharged Home and Referred for Elective Angioplasty in the Future	Total Cases
2008	44	1	0	0	0	0	45	9	54
2009	71	0	1	1	1	0	74	5	79
2010	51	0	2	0	1	0	54	10	64

*Number of transfers to another institution between October 1, 2011 and December 31, 2011

Source: Greenwich Hospital Cardiology Department

Therefore, in total since FY 2008, 272 patients sought invasive cardiac care at Greenwich Hospital but could not access the necessary services in their local community. As a result of this lack of access, there are several adverse patient implications. First, the lack of access to elective angioplasty at Greenwich Hospital means that these patients received two invasive procedures instead of one since their diagnostic cardiac catheterization was performed at Greenwich Hospital and a

subsequent angioplasty was performed at a second facility. This results in increased risk for infection, delays in receiving the care required, and additional costs for a second procedure. Second, patients who were medically fragile, were subjected to transport to another facility. Third, transferring patients to another facility creates an unnecessary stressful and uncomfortable situation for patients and family. Fourth, transferring to another facility is an increased stress for the patients and their families with regard to transportation. For some, in Greenwich Hospital's greater service area, transportation outside the service area is problematic.

Greenwich Hospital Must Address the Cost-Effectiveness of Angioplasty Services
As previously described, service area residents who obtain a cardiac catheterization at Greenwich Hospital and require a subsequent angioplasty procedure must undergo two invasive procedures at two institutions. This practice increases the costs of care to patients and payers and ultimately to the health care system as a whole. Patients have to incur the additional out of pocket costs for the second procedure as well as additional transportation costs for themselves and possibly also family members. With patients receiving two procedures at two separate institutions, payers have increased expenses for the care provided to patients. Eliminating a second invasive cardiac procedure would improve the cost-effectiveness of angioplasty services for service area residents.

Primary angioplasty is a critically needed, lifesaving service that the Hospital provides to the community. Greenwich Hospital made significant investments in its primary angioplasty program in order to provide a necessary service to its service area, however, the costs of operating such a small program impede the Hospital's efforts to provide cost-effective care. An agreement is in place with the Yale School of Medicine to provide 24/7 coverage at the Hospital so that a highly skilled interventional cardiologist is always either on-site or in close proximity should a patient be in need of primary angioplasty. Greenwich Hospital is responsible for paying $1.78 million per year to the Yale School of Medicine to provide physician staffing for the primary angioplasty program. While this physician model is an essential component of the primary angioplasty program, it results in significant staffing costs to cover approximately 40 primary angioplasty cases treated at the Hospital each year. Allowing these same physicians to also perform elective angioplasty at Greenwich Hospital would be a cost-effective and efficient approach and would reduce the costs per case from the current arrangement. Since the current physician staffing covers 24/7, no additional physician expense is required to add elective angioplasty. Therefore this proposal represents a cost-effective solution to angioplasty services in Greenwich Hospital's service area.

The Proposed Program will Improve the Quality of Care of Elective Angioplasty Services Provided to Greenwich Hospital Service Area Patients
Greenwich Hospital's partnership with clinical faculty from the Yale School of Medicine and its membership in the Yale New Haven Health System will improve the quality of elective angioplasty services to Greenwich Hospital service area residents. As previously noted, service area residents who present to or desire elective angioplasty treatment at Greenwich Hospital are subjected to transfer to another Connecticut hospital and a second invasive procedure or may receive their care at a

New York hospital. The transfer process, additional procedures, and transportation out-of-state do not constitute high quality service or a positive patient experience. The term elective angioplasty is misleading as patients may have unstable, acute coronary symptoms, yet must be called elective since they do not meet the criteria for emergency angioplasty for STEMI. The proposed program will allow service area residents to remain in the local community and obtain elective angioplasty services from some of the nation's leading interventional cardiologists.

Greenwich Hospital's partnership with the clinical faculty from the Yale School of Medicine (YSM) has been a key factor in the success of its primary angioplasty program. The program is staffed by some of the nation's leading interventional cardiologists, who maintain a busy clinical practice, and many of whom perform angioplasty procedures far in excess of the minimum national standards each year. These clinicians are familiar with the Hospital's medical staff and operations. They also bring with them the procedures, clinical protocols and safety standards that are in place at Yale-New Haven Heart and Vascular Center, one of the Northeast's and nation's leading programs. In addition, the interventional cardiologists from YSM currently perform elective angioplasty procedures both at Yale-New Haven Hospital and at the West Haven VA, and are highly skilled in performing the procedure, with demonstrated outcomes that attest to their excellent quality. In fact, these same physicians are providing care to the majority of patients who currently must be transferred from Greenwich Hospital to Yale New Haven Hospital to receive elective angioplasty. Providing elective angioplasty at Greenwich Hospital will allow patients to receive the same high quality care from the same physicians without having to incur the stress of transfers and second procedures.

Greenwich Hospital has been a member of Yale New Haven Health System (YNHHS) for over twelve years. As Yale New Haven Health System has evolved, it has expanded the degree of clinical integration among its corporate members (Bridgeport Hospital, Greenwich Hospital, Yale-New Haven Hospital, and Northeast Medical Group). This clinical integration, which brings significant benefits, including consistent approaches towards clinical quality and safety practices, staffing and training, information systems, knowledge sharing and best practices, is expected to continue. Quality and outcomes will be predictable across YNHHS sites because identical care management and clinical protocols will be followed.

In addition, YNHHS is in the process of implementing the Epic common electronic medical record. This will have a major impact on YNHHS' ability to better coordinate care and services as well as easily implement and monitor best practice policies and procedures among its members, as there will be a shared medical record among all three hospitals and its clinicians. There will be a seamless flow of information within YNHHS and other providers/settings including community physicians. Providers at one site will be able to access information on a patient's visit to a different System hospital. For example, patients that are treated at both Greenwich Hospital and Yale-New Haven Hospital will share a common medical record, allowing clinicians at both sites to have 24/7 access to the most up-to-date clinical information on patients. Such integration would benefit the small number of angioplasty patients that may have to be transferred to YNHH but were also treated at Greenwich Hospital. The

implementation of Epic and the corresponding changes in System-wide processes will also facilitate the easy capture and analysis of data to support performance improvement, outcomes management, public reporting and transparency. Epic will help ensure that regulations and organizational policies and procedures regarding security, privacy and compliance are met. This will enable the Yale-New Haven Heart and Vascular Center to continue to monitor and develop all appropriate standards, protocols, policies, procedures and quality assessments which will be followed by Greenwich Hospital in providing angioplasty services to patients.

Conclusion of Public Need

Based on all of the above factors, the proposed elective angioplasty program at Greenwich Hospital, as a satellite of the Yale-New Haven Heart and Vascular Center, will be an appropriate, cost-effective, high quality program that is consistent with clinical guidelines, recent research and the approach currently being followed in many other states and at many other hospitals. Greenwich Hospital is well-prepared to embark on this project given the existing and proposed infrastructure and the program's success in treating more acutely ill patients with primary angioplasty. The program would be part of the Yale-New Haven Heart and Vascular Center, therefore it would comply with its rigorous standards and requirements, and provide patients with the ability to receive elective angioplasty locally at Greenwich Hospital, where they can benefit from high quality care and continuity, and avoid the complications and stress of transfer.

b. Provide the following regarding the proposal's location:

i. The rationale for choosing the proposed service location;

Greenwich Hospital is a progressive institution offering a wide range of medical, surgical, diagnostic and preventive programs with outstanding results. The Hospital currently provides diagnostic cardiac services including echocardiography, nuclear cardiac imaging, stress testing, cardiac CT angiography, and diagnostic cardiac catheterization. In addition, Greenwich Hospital offers interventional cardiac services to provide primary angioplasty for acute myocardial infarction (MI) patients pursuant to the Hospitals' authorization to provide primary angioplasty service under OHCA CON approval (DN 08-30148-MDF). The Hospital also has a cardiac rehabilitation program with inpatient and outpatient components for post-hospital follow-up care. A detailed list of services is below:

Ambulatory BP monitor	Arterial Doppler (PVR)
Cardiac Rehabilitation	Diagnostic Cardiac Catheterization
EKG Stress tests	Electrical Cardioversions
Peripheral angiography/intervention	Event Loop Recorder Implant
Electrophysiology Study	Holter monitor (24 and 48 hour)
Fetal Echocardiograms	Intravascular Ultrasound of Coronary/ Fractional Flow Reserve
Implantable Cardiac Defibrillator	Percutaneous Coronary Intervention in the event of an MI Alert
Nuclear Stress Tests	Permanent/Temporary Pacemakers
Pericardiocentesis	Trans-esophageal Echocardiograms (with bubbles)
Pharmacological Stress Echocardiograms (Dobutamine)	Trans-esophageal Echocardiograms (without bubbles)
Trans-thoracic Echocardiograms	Stress Echocardiograms

Greenwich Hospital is a logical location for the proposed elective angioplasty program for a multitude of reasons. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital. The Greenwich Hospital cardiac services program, which offers high quality diagnostic cardiac catheterization and primary angioplasty, is already a satellite under the medical direction of the Yale-New Haven Heart and Vascular Center, and employs a YSM medical director as well as YSM medical staff available 24 hours per day, 7 days per week. The Hospital is a longstanding member of Yale New Haven Health System, which will allow it to benefit from continued System-wide clinical integration, collaboration and sharing of best practices.

Patients prefer to be treated locally, close to their residence and family members. For patients in the Greenwich Hospital service area, the option to receive elective angioplasty care at their local hospital, namely Greenwich Hospital, is not available to them. Referring physicians prefer to send a patient in need of interventional cardiology to a facility that can perform both diagnostic cardiac catheterization and elective angioplasty to avoid the need for the patient to be transferred and be re-catheterized if an angioplasty is required. As a result, these patients often bypass Greenwich Hospital entirely although the Hospital is fully equipped to provide services and is an excellent local option for patients.

The lack of elective angioplasty at Greenwich Hospital results in disruptive care for patients. Under the current arrangement, Greenwich Hospital patients have to be transferred to other hospitals for elective angioplasty procedures even though experienced YSM interventional cardiologists and catheterization lab support staff are onsite and available 24 hours every day to provide the needed care at Greenwich Hospital. The vast majority of patients are transferred to Yale-New Haven Hospital, where they are treated by the same physicians from whom they would have received the same care at Greenwich Hospital if Greenwich Hospital was approved to provide elective angioplasty.

In light of these considerations, as well as the previously mentioned trends in many states to allow elective angioplasty without on-site surgery, Greenwich Hospital is an appropriate location for the proposed program.

ii. The service area towns and the basis for their selection;

The primary and secondary service area towns represent those communities which comprise 85% of Greenwich Hospital's inpatient volume. They include:

Connecticut Towns
Darien, Greenwich, New Canaan, Norwalk, Stamford, Weston, Westport and Wilton.

New York Towns
Armonk, Bedford, Bedford Hills, Harrison, Hartsdale, Katonah, Larchmont, Mamaroneck, Mount Kisco, Mount Vernon, New Rochelle, Port Chester, Pound Ridge, Purchase, Rye, Scarsdale, South Salem, West Harrison and White Plains.

The Hospital and its physicians treat many patients with heart disease who live in these service area towns and the proposed elective angioplasty program would serve to provide better access to, and coordination of, cardiac care.

iii. The population to be served, including specific evidence such as incidence, prevalence, or other demographic data that demonstrates need;

Incidence of Cardiovascular Disease
Major cardiovascular disease was the leading cause of death in Connecticut according to Department of Public Health Crude and Age-Adjusted Mortality Rate data for 2006-2008. According to the Connecticut Department of Public Health most recently published *Connecticut Resident Hospitalizations, 2009* report, diseases of the circulatory system totaled 58,853 and diseases of the heart totaled more than 40,000 discharges. There were more than 6,300 discharges for acute myocardial infarction (AMI). As shown in the Table H-5 below, diseases of the heart were the leading causes of hospitalizations for all ages combined, as well as for ages 65 and older in 2009.

Table H-5
CONNECTICUT RESIDENT HOSPITALIZATIONS, 2009
Leading Causes of Hospitalization (Numbers of Hospitalizations) by Age and Sex[a]

Sex	Rank	Age group (Years)						
		0-4	5-14	15-24	25-44	45-64	65+	All ages
Both sexes	1	Respiratory (3,053)	Mental (1,890)	Mental (4,741)	Mental (10,308)	Digestive (12,592)	Heart (27,430)	Heart (40,484)
	2	Injury/Poisoning (619)	Respiratory (1,433)	Injury/Poisoning (2,265)	Digestive (7,437)	Heart (10,902)	Respiratory (19,692)	Digestive (38,952)
	3	Endocrine[c] (503)	Digestive (1,082)	Digestive (2,244)	Injury/Poisoning (4,948)	Mental (10,649)	Digestive (15,138)	Respiratory (36,804)
	4	Digestive (459)	Injury/Poisoning (809)	Respiratory (982)	Genitourinary (3,284)	Musculoskeletal (9,630)	Injury/Poisoning (13,634)	Injury/Poisoning (30,873)
	5	Infectious (372)	Anemias/Blood (326)	Endocrine[c] (631)	Respiratory (2,964)	Respiratory (8,680)	Genitourinary (10,684)	Mental (30,160)
	6	Nervous (354)	Endocrine[c] (315)	Genitourinary (622)	Musculoskeletal (2,945)	Injury/Poisoning (8,598)	Musculoskeletal (10,660)	Musculoskeletal (23,905)
	7	Skin (290)	Nervous (311)	Anemias/Blood (586)	Endocrine[c] (2,894)	Neoplasms[b] (7,928)	Neoplasms[b] (8,371)	Genitourinary (20,495)
	8	Genitourinary (286)	Musculoskeletal (236)	Infectious (469)	Neoplasms[b] (2,483)	Genitourinary (5,401)	Infectious (8,246)	Neoplasms[b] (19,212)
	9	Anemias/Blood (208)	Genitourinary (218)	Nervous (421)	Heart (1,883)	Endocrine[c] (5,002)	Cerebrovascular (6,865)	Endocrine[c] (15,222)
	10	Neoplasms[b] (85)	Skin (211)	Musculoskeletal (391)	Infectious (1,456)	Infectious (3,566)	Endocrine[c] (5,877)	Infectious (14,312)

[a] See Appendix and Table H-1 for corresponding diagnostic groups by ICD-9 CM codes.

[b] Includes both benign and malignant neoplasms.

[c] Endocrine, nutritional, metabolic, and immunologic disorders, including diabetes mellitus and volume depletion (dehydration).

According to the Connecticut Department of Public Health Office of Health Care Access' report 'The Burden of Cardiovascular Disease in Connecticut 2010 Surveillance Report' Executive Summary (included as Attachment IV):

- **Cardiovascular diseases (CVDs) are a great public health concern. CVD account for about one-third of all Connecticut resident deaths. Coronary Heart Disease (CHD), cerebrovascular disease (stroke) and heart failure (HF) are the main types, accounting for 48%, 15% and 8% respectively of all CVD deaths.**
- **Cardiovascular disease accounted for about 33% (9,351) of all Connecticut resident deaths in 2008, as shown in the table below.**

Connecticut Resident Deaths, 2008

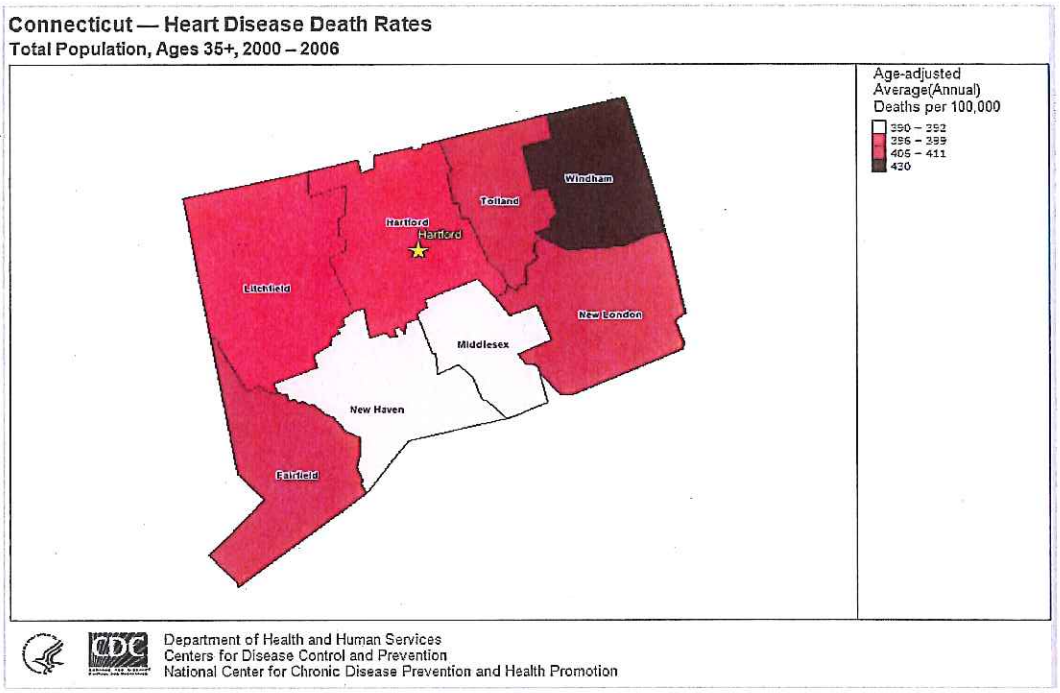
Cause of Death	Number of Deaths	Percent of Deaths
All Causes	28,749	100%
Cardiovascular Disease	9,351	33%
Cancer	6,765	24%
Chronic Liver Respiratory Disease	1,494	5%
Unintentional Injury	1,362	5%
Alzheimer's Disease	831	3%
Pneumonia and Influenza	688	2%
Diabetes	618	2%

Source: Connecticut Department of Public Health Office of Health Care Access; The Burden of Cardiovascular Disease in Connecticut 2010 Surveillance Report, March 2011

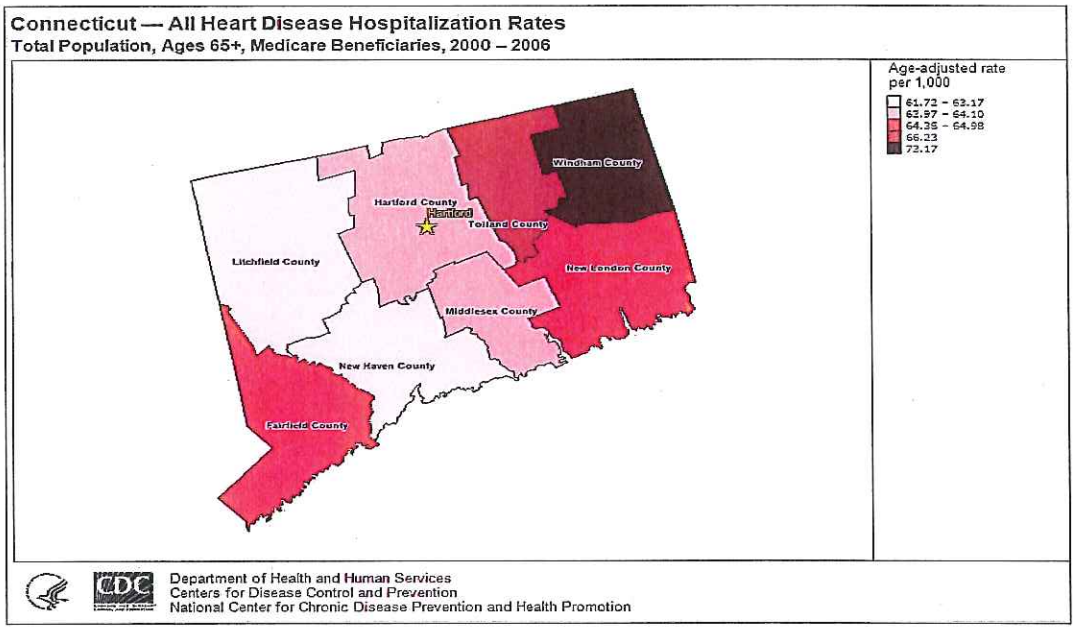
- **About $2.2 billion was billed for CVD hospitalizations in Connecticut in 2008. Approximately 34% of CVD charges are for CHD, 12% for stroke and 12% for HF. CVD also incurs enormous indirect costs.**
- **About 18% of all hospital discharges in Connecticut are due to CVD. Approximately 26% of CVD hospitalizations are due to CHD, 12% to stroke and 18% to HF (2008 data).**

The following maps show the heart disease death rate in Connecticut by county for 2000 – 2006. Fairfield County's heart disease death rate was higher than the rates in New Haven, Middlesex, Hartford and Litchfield Counties. Between 2000 and 2006, Fairfield County had the third highest 65+ heart disease hospitalization rate per 1,000 age-adjusted and spatially smoothed in Connecticut.

Heart Disease Death Rates Map



Heart Disease Hospitalization Rates Map



Service Area Demographics

The following table shows population projections for Greenwich Hospital's Connecticut and New York service area towns. The total service area will consist of over 370,000 people in Connecticut and 440,000 people in New York, of whom approximately 43% are over age 45. Because of Greenwich Hospital's location on the border of Connecticut and New York, it attracts a significant number of New York residents, who constitute a sizable proportion of the Hospital's patient population.

The proportion of Greenwich Hospital's service area patients who are over age 45 and the patients over age 65 are projected to increase between 2011 and 2016, as shown in the population table below. Both the risk and rate of heart disease increase with age, as does the corresponding need for interventional cardiology services.

Population Projections
Greenwich Hospital Service Area

Area & Age Cohort Service Area	2000	2011	2016	% Change 2000 - 2011	% Change 2011 - 2016
0-44	486,078	463,790	454,100	-4.6%	-2.1%
45-54	110,947	131,685	123,671	18.7%	-6.1%
55-64	75,351	101,043	115,399	34.1%	14.2%
65-74	56,212	60,212	72,416	7.1%	20.3%
75-84	37,209	37,304	37,086	0.3%	-0.6%
85+	14,641	18,174	19,883	24.1%	9.4%
Total	780,438	812,208	822,555	4.1%	1.3%
Ages 45+	294,360	348,418	368,455		
Ages 65+	108,062	115,690	129,385		
% 45+	37.7%	42.9%	44.8%		
% 65+	13.8%	14.2%	15.7%		

Source: Claritas

iv. How and where the proposed patient population is currently being served;

Patients from the Greenwich Hospital service area that require elective angioplasty currently go to another hospital in either Connecticut or New York to receive these services. This includes patients who receive a diagnostic cardiac catheterization at Greenwich Hospital and who subsequently require elective angioplasty as well as Greenwich Hospital primary angioplasty patients who have coronary artery disease in other vessels and require a subsequent elective angioplasty. The vast majority of these patients are transferred to Yale-New Haven Hospital and some are treated at White Plains Hospital, Columbia, Cornell and Westchester Medical Center.

Some physicians who currently utilize Greenwich Hospital services to provide care to their patients are often reluctant to direct their patients to the Greenwich Hospital cardiac catheterization lab if there is a clinical suspicion that the patient may require

angioplasty. Currently Greenwich Hospital can only address the culprit lesion for patients in need of emergency angioplasty.

As a satellite of a leading academic medical center's nationally recognized cardiac program, the Greenwich Hospital elective angioplasty program would extend the quality, safety and leading clinical advances of the Yale-New Haven Heart and Vascular Center to its patients and community. The proposed program will adhere to the same rigorous clinical, operator and institutional criteria and monitoring as the YNHH program. Consequently, the program will assure high quality outcomes, care continuity, state-of-the-art, easily accessible and high quality care.

v. All existing providers (**name, address, services provided**) of the proposed service in the towns listed above and in nearby towns;

Stamford Hospital, located at 30 Shelburne Road, Stamford CT 06904 and White Plains Hospital, located at 41 E. Post Road, White Plains, New York 10601 offer elective angioplasty in the service area.

vi. Describe existing referral patterns in the area to be served by the proposal; and

Patients are referred to Greenwich Hospital's cardiology program by their internist or cardiologist. Current referral patterns are with cardiologists within the service area and on the medical staff of Greenwich Hospital. Currently, the cardiologists (including interventional cardiologists) on the medical staff at Greenwich Hospital have practices located in Greenwich, CT (55%), Westchester County, NY (13%) and Stamford, CT (11%). The YSM physicians practicing at the Greenwich Hospital location are included in the Greenwich, CT statistics above.

vii. The effect of the proposal on existing providers, explaining how current referral patterns will be affected by the proposal.

The vast majority of patients who must be transferred from Greenwich Hospital to another hospital for elective angioplasty are sent to Yale-New Haven Hospital. Therefore, a significant proportion of the Greenwich Hospital proposed program volume will represent cases that would previously have been transferred to Yale-New Haven Hospital. This reduction in volume at Yale-New Haven Hospital has been agreed to by clinical and administrative leadership and will not negatively impact Yale-New Haven Hospital's cardiac services.

Recent discussions with the Hospital's current physician referral sources indicate that they support the provision of elective angioplasty at Greenwich Hospital, as it will allow their patients to receive their interventional cardiac care at Greenwich Hospital. Letters of support from members of the Greenwich Hospital medical staff attest to physicians' endorsement of the proposed program and are included in Attachment V.

c. Explain why the proposal will not result in an unnecessary duplication of existing or approved health care services.

The proposal will not result in unnecessary duplication of existing or approved health care services. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital for the primary angioplasty service.

d. The record in this docket will include, in addition to other materials, the American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines. The Applicants may submit any comments in response to this evidence, which they deem appropriate.

Please see Attachment VI. Knowledge and processes related to elective angioplasty continue to evolve. As previously noted, increasing and significant evidence exists for elective angioplasty programs at facilities without on-site surgical backup. The November 7, 2011 updated ACC/AHA/SCAI angioplasty guidelines have upgraded the recommendation level for elective angioplasty programs without cardiac surgery back-up. Greenwich Hospital and Yale-New Haven Hospital adhere to these guidelines, which are incorporated into relevant policies and procedures.

e. If applicable to the proposal (e.g. establishment of cath lab without a cardiac surgical program), provide a copy of a signed agreement between the Applicant and a tertiary care facility. Identify patient selection guidelines, the process and protocols involved in the transfer of a patient requiring cardiac surgery, and joint quality assurance reviews and joint training.

A copy of the signed agreement between Greenwich Hospital and YNHH can be found in Attachment VII. The agreement addresses patient selection, emergency transfer, joint quality assurance and training.

f. Has the Applicant held any discussions with the local emergency medical service ("EMS") regarding the proposed service? Describe.

Greenwich Hospital had discussions with the Greenwich Emergency Services (GEMS) and the Emergency Medical Services companies servicing Port Chester, Rye and Harrison, New York about the proposed program, and received favorable responses from all parties.

3. Projected Volume

a. In table format, provide historical volumes (three full years and the current year-to-date) for each Applicant by service; by zip code; by inpatient/outpatient; and by unique physician identifier as applicable to the proposal.

<u>Volume by Service and Inpatient/Outpatient</u>
Historical volume for Greenwich Hospital primary angioplasties is shown in the table below.

Total Greenwich Hospital Primary Angioplasty Cases

	FY 2008	FY 2009	FY 2010	FY 2011	FY 2012*
Total Angioplasty	40	40	32	38	15
Note: All angioplasties are inpatient					

*Note: Actual Q1 volume (October – December); annualized volume would equal 60
Sources: CHIME and Greenwich Hospital Department of Cardiology

Volume by ZIP Code

Historical volume for Greenwich Hospital primary angioplasties is shown in Attachment VIII

Volume by Unique Physician Identifier

Historical volume for Greenwich Hospital primary angioplasties broken out by unique physician identifier is shown in the table below.

Total Greenwich Hospital Primary Angioplasty Cases by Unique Physician Identifier

	Angioplasty by Unique Physician Identifier				
MD	**FY 2008**	**FY 2009**	**FY 2010**	**FY 2011**	**FY 2012***
A	1	0	0	0	0
B	1	1	1	0	0
C	1	0	0	0	1
D	2	3	0	0	0
E	0	1	1	1	0

Total	**40**	**40**	**32**	**38**	**15**

*Note: Actual Q1 volume (October – December); annualized volume would equal 60
Sources: CHIME and Greenwich Hospital Department of Cardiology

b. If applicable, for the most recently completed fiscal year, identify the number of:

i. Patients with a diagnosis of ST-segment elevation acute myocardial infarction (AMI) that presented at the Hospital's emergency room

In FY 2011, there were 57 patients that presented to Greenwich Hospital's emergency department who triggered an MI Alert with a suspected diagnosis of ST-segment elevation acute myocardial infarction.

ii. Doses of thrombolytic medication, issued through its pharmacy, to patients with a diagnosis of AMI.

In FY 2011, there were zero doses of thrombolytic medication issued through the pharmacy to patients with diagnosis of AMI. In acute MI, thrombolytics are typically only used if emergency angioplasty cannot be done in a timely manner. Greenwich Hospital did not use thrombolytics for acute MI during the past year because the Hospital brought these patients to the cardiac catheterization lab in a timely fashion, which is the clinically preferred treatment for patients.

c. In table format, provide projected volumes (three full years) for each Applicant by service; by inpatient/outpatient; and by unique physician identifier as applicable to the proposal.

The tables below provides historical and three full years of projected volumes by inpatient/outpatient.

Due to the unscheduled nature of primary angioplasty cases and the scheduling rotation for the interventional cardiologists, it is difficult to project future volumes by unique physician identifier.

CON Elective Angioplasty Volume Projections

Angioplasty Volumes at Greenwich Hospital
Historical and Projected Volumes

Volumes	FY08 Actual	FY09 Actual	FY10 Actual	FY11 Actual	Year 1	Year 2	Year 3
Primary Angioplasty Cases	40	40	32	38	38	38	38
Elective Angioplasty Cases To Be Performed at GH (currently sent to other facilities)	0	0	0	0	53	53	53
Elective Angioplasty Cases Transferred or Referred to Another Facility	54	79	64	59	0	0	0

Outpatient Angioplasties (10.4%)	20	23	25
Total	196	217	242

Source: CHIME database

d. Provide a detailed description of all assumptions used in the derivation/calculation of the projected volumes.

The angioplasty projections include primary angioplasty cases currently treated at the Hospital and elective angioplasty cases currently not treated at the Hospital.

Greenwich Hospital currently provides primary angioplasty to patients that meet the criteria for care. For the past several fiscal years, this volume has remained fairly stable. In FY11, the Hospital had 38 primary angioplasty cases. This is the same number as the four year average number of cases. This volume was projected to remain stable over the next several years. In the first quarter of FY12, the Hospital provided 15 primary angioplasties which would project to 60 annual primary angioplasties. To be conservative, projections were based on the last several fiscal years where 12 months of data was available for each year.

While the Hospital does not provide elective angioplasty at this time, there are patients who present to the Hospital each year that require elective angioplasty. These patients are either transferred or referred to another facility for care. The number of transfers or referrals for the past four fiscal years has been 54, 79, 64 and 59 respectively. Over the past four fiscal years, on average there had been 64 patients per year either transferred or referred to another facility for care. With the approval of this application, Greenwich Hospital would be able to provide elective angioplasty to the majority of these patients and thus save the patients an unnecessary transfer or referral to another facility. These patients are already part of the Greenwich Hospital physician referral patterns established at the Hospital that would continue when the Hospital is approved to provide elective angioplasty care. However, there is a small portion of patients that would need to be transferred or referred to another facility even if Greenwich Hospital was approved to provide elective angioplasty.

In the CPORT E trial, (discussed elsewhere in the CON) of patients who underwent primary angioplasty, 12% were excluded from randomization after consenting to the study, representing the subgroup who would be transferred to another facility. In reviewing the cases in FY09-11 that were either transferred or referred for care to another facility, it was felt that some of the cases would have been transferred or referred even if Greenwich Hospital was approved to provide elective angioplasty. These percentages for FY09-11 were respectively 12%, 16% and 22% for a three year average of 16.6%. For the projection of elective angioplasty at Greenwich Hospital, the conservative estimate of 16.6% was used, i.e. 83.4% of patients who had been transferred or referred to another facility in the past would be able to receive care at Greenwich Hospital. This percentage applied to the average of 64 patients per year transferred or referred to another facility yielded 53 patients in Year 1 who would be able to stay and receive their care at Greenwich Hospital. Again, to be conservative, this volume was projected to remain stable over the next several years.

Because Greenwich Hospital does not currently provide elective angioplasty services, physicians are reluctant to send their patients for cardiac catheterizations to the Hospital in case the patient will require an elective angioplasty and then have to be

transferred or referred to another facility. The Hospital conducted a telephone survey of cardiologists currently on the Hospital's medical staff. The cardiologists were asked to estimate the number of additional patients they might send to Greenwich Hospital for cardiac catheterizations if the Hospital received approval to offer elective angioplasty. In addition, some internal medicine physicians send patients directly for cardiac catheterizations to a hospital instead of to a cardiologist. The Hospital conducted a survey of the large internal medicine practices on the medical staff. These physicians were also asked to estimate the number of additional patients they might send to Greenwich Hospital.

Lastly, the cardiology practice that is part of the YNHHS cardiology program at Greenwich Hospital estimated the number of patients each year that they send directly to Yale-New Haven for cardiac catheterizations instead of to Greenwich Hospital. These patients numbered 25, 22, 21 and 25 in FY08-11 respectively for an average of 24 per year. These patients would use Greenwich Hospital if the Hospital provided elective angioplasty services. Based on the information above, 257 additional cardiac catheterizations were estimated to be sent to Greenwich Hospital for care if the Hospital provided elective angioplasty services. The surveyed physicians who indicated they would send additional cardiac catheterizations have practices located in Greenwich, Connecticut or in Westchester County, New York.

In order to estimate the number of angioplasties resulting from the additional cardiac catheterizations, the ratio of angioplasties to cardiac catheterizations was analyzed. Since primary angioplasties and elective angioplasties have the same codes, it was not possible to separate them into two categories so angioplasty volume includes both primary and elective angioplasty cases. Angioplasty volume and cardiac catheterization volume includes both inpatient and outpatient cases. New York angioplasty and cardiac catheterization outpatient historical volumes were not available from the state of New York for CY08 and for CY11 only the first five months of inpatient and outpatient data was available. Therefore, CY11 New York data was flat line projected to estimate the entire year.

The ratios of angioplasties to cardiac catheterizations were determined for Greenwich Hospital (35.4%), Yale-New Haven Hospital (45.3%), the state of Connecticut (36.3%) and the Greenwich Hospital service area (41.2%). The Greenwich Hospital average included patients transferred or referred to another facility. While the program at Greenwich Hospital will follow all of the policies, procedures and guidelines of the Yale-New Haven Heart and Vascular Center, the New Haven facility is a tertiary hospital and may see a higher rate of angioplasty/sicker patients. To be conservative, an average ratio (41.0%) of the Yale-New Haven Hospital ratio and state of Connecticut ratio was used to estimate the number of angioplasties resulting from the cardiac catheterizations. The 41.0% ratio was applied to the 256 potential angioplasties to yield an estimated 105 new referred angioplasty cases to Greenwich Hospital in Year 1 from cardiologists on the Hospital medical staff who would previously have sent the cases either to Yale-New Haven Hospital or a New York hospital. It is expected that this volume would increase 21 and 25 angioplasties respectively in Years 2 and 3 as the Greenwich Hospital program becomes established. The increases would represent less than 1 angioplasty per year from each of the

cardiologists on the medical staff of Greenwich Hospital. Since the patients will be referred by the cardiologists on the Greenwich Hospital medical staff, it is expected that the majority of patients will be from New York or Greenwich, Connecticut. The increase in volume results from several factors including the addition of New York interventional cardiologists who currently do not practice at Greenwich Hospital but have referral relationships with the cardiologists on the Hospital medical staff, increased physician comfort with elective angioplasty care at the Hospital and patient preference for the high quality care offered at Greenwich Hospital.

In FY11, inpatient angioplasties were 89.6% of total angioplasties according to the latest available data from the CHIME database. This percentage was used to estimate the distribution of angioplasties at Greenwich Hospital in Years 1, 2 and 3.

e. Provide a copy of any articles, studies, or reports that support the statements made in this application justifying need for the proposal, along with a brief explanation regarding the relevance of the selected articles.

In addition to previous studies and reports referenced, Attachment IX contains some additional supporting materials. Key points from each document are summarized below.

Document/Article	Key Points
Atlantic Cardiovascular Patient Outcomes Research Trial presentation	**"In hospitals without on-site cardiac surgery that complete a formal PCI development program, adhere to C-PORT participation requirements, and whose outcomes are monitored, non-primary PCI is safe and associated with similar rates of adverse events including mortality"**
American Heart Association /American Stroke Association CPORT-E Trial Summary	**Summarizes results of CPORT-E Trial: "Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without cardiac surgery capabilities fared as well as those in hospitals that did."**
2011 ACC/AHA/SCAI Guideline for Percutaneous Coronary Intervention	**Provides additional explanation and documentation of the 2011 guidelines and shows classification of recommendations and levels of evidence.**
The Advisory Board Daily Briefing On-site Surgery Not Necessary to Perform Elective PCI, November 18, 2010	**Summary of Atlantic CPORT-E Trial. Conclusion "The findings ultimately may prompt regulatory changes that could effectively decouple PCI and open heart surgery, allowing more flexibility for hospitals pursuing a regionalization strategy."**

f. Please identify the number of physicians that will be providing coverage for the proposed program. Explain whether the physicians will be full time with the proposed program or also providing coverage at other hospitals.

Physician coverage for the proposed elective angioplasty program will be similar to the existing 24/7 coverage for the primary angioplasty program. Coverage will be provided by privileged medical staff associated with either YSM Department of Cardiology, members of which currently practice at Greenwich Hospital as part of the existing primary angioplasty program, or members of the Greenwich Hospital medical staff with privileges in performing angioplasties. At this time, coverage will be provided by eleven interventional cardiologists from the Yale School of Medicine. At least one physician will be full time at Greenwich Hospital weekdays and on call nights and weekends. The on call physician will be in close proximity to Greenwich Hospital for immediate response to the Hospital during nights and weekends. When on call, the physician will only be covering Greenwich Hospital. The members of the YSM Section of Interventional Cardiology also provide coverage at Yale-New Haven Hospital, the West Haven VA and Lawrence & Memorial Hospital's primary angioplasty program.

4. Quality Measures

a. Submit a list of all key professional, administrative, clinical, and direct service personnel related to the proposal. Attach a copy of their Curriculum Vitae.

Please see Attachment X for copies of Curriculum Vitae.

b. Explain how the proposal contributes to the quality of health care delivery in the region.

The current population served through Greenwich Hospital's primary angioplasty program is limited to patients that present on an emergent basis with ST segment

elevation MI or new onset left bundle branch block. This proposal would provide local access to patients requiring interventional cardiology services on an elective and urgent basis as well as the emergent patients who currently have access to these services. Patients from the Greenwich Hospital service area that require elective angioplasty are currently required to go to another hospital to receive these services, which adds additional stress for patients and their families, particularly unnecessary due to the presence of highly qualified interventional cardiologists and staff available onsite. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital. As discussed in the public needs section, the current practice of transferring patients who require elective angioplasty has potential negative implications to patient care quality and safety. As well, the majority of these patients are transferred to Yale-New Haven Hospital, where they are treated by the same physicians from whom they would have received the same care at Greenwich Hospital if Greenwich Hospital was approved to provide elective angioplasty.

Greater System-wide clinical integration, through the proposed closer integration of Greenwich Hospital's cardiac services with the Yale-New Haven Heart & Vascular Center and partnership with the Yale School of Medicine will have a positive impact on the quality of health care delivery in the region. The Yale-New Haven Heart & Vascular Center will provide medical and clinical direction, education, training and management and oversight to ensure the delivery of the highest quality care. In addition, the use of the Epic common electronic medical record and combining best practices at both campuses to enhance clinical quality and patient safety through standardized procedures and practices.

<u>Greenwich Hospital's High Quality Cardiac Program</u>
The most recent ACC/AHA/SCAI guidelines have and will continue to guide Greenwich Hospital in the operation of its angioplasty program. A copy of the guidelines is attached (Attachment VI).

Greenwich Hospital participates in the National Cardiovascular Data Registry NCDR – CathPCI Registry®. Launched by the American College of Cardiology (ACC) in 1995, the "ACC National Cardiovascular Data Registry: (ACC-NCDR™) is a result of the ACC's exploration of various strategies for collecting and implementing clinical data in order to improve cardiovascular care. This database includes the implanted cardiac defibrillator registry as well as a heart catheterization registry (which further breaks down to both diagnostic and interventional procedures). The information gathered from this database allows the ACC to set benchmarks that enable facilities to see where they are deficient and therefore improve upon performance. There are currently 1,380 sites that participate in the catheterization registry.

In addition, both the primary angioplasty program, which has been in place at Greenwich Hospital since 2005, and the diagnostic cardiac catheterization laboratory, have achieved outcomes that are consistent with many larger tertiary facilities. For the four quarters ending mid-2011, 100% of STEMI patients received immediate angioplasty within 90 minutes, which meets/exceeds national standards for this measure. Other strong clinical outcomes of the Greenwich Hospital primary

angioplasty program, for the four quarters ending mid-2011, are shown in the following table.

National Cardiovascular Data Registry Institutional Outcomes
Executive Summary
Greenwich Hospital
Rolling Four Quarters Ending 2011 Q2

Section II: Quality Metrics			
Metric	Greenwich Hospital	All Hospitals 50th Percentile	All Hospitals 90th Percentile
PCI Process Metrics			
Median time to immediate PCI for STEMI patients (in minutes)	67.0	63.1	50.4
Proportion of STEMI patients receiving immediate PCI within 90"	100%	91.4%	100%
Proportion of patients with aspirin prescribed at discharge	100%	98.2%	99.9%
Proportion of patients with thienopyridine prescribed at discharge	100%	99.1%	100%
Statins prescribed at discharge	100%	91.5%	97.3%
Utilization Metrics			
Median post-procedure length of stay (in days) for PCI patients with STEMI	2.0	2.7	1.7

Source: National Cardiovascular Data Registry® – CathPCI Registry® - Executive Summary – Greenwich Hospital Compared to Rolling Four Quarters for All Hospitals Ending 2011Q2. Aggregation Date: September 30, 2011 Published Date: October 19, 2011

The ACC-NCDR database has limitations on the comparative use of its angioplasty data. However, at this time the ACC-NCDR data is the only benchmarking data set available to hospitals. The ACC-NCDR reports provide comparative benchmarking for all participating programs, and do not separately benchmark programs that provide only primary angioplasty such as Greenwich Hospital. As a result, the report shows an "apples to oranges" comparison of data. Greenwich Hospital's performance is benchmarked against programs that have significantly higher volumes that include elective angioplasty cases. As well, primary angioplasty cases tend to be more medically unstable in comparison to elective angioplasty cases. Greenwich Hospital contacted NCDR but the organization was not able to provide the Hospital with data listed separately for primary versus elective angioplasty. Greenwich Hospital's most recent complete ACC-NCDR report is included as Attachment XI. A letter from Greenwich Hospital to the Office of Health Care Access dated March 9, 2011 that discusses the limitations of comparing Greenwich Hospital's primary angioplasty outcomes with larger programs that offer elective angioplasty, is included as Attachment XII.

Even given the limitations of the angioplasty data, it is clear that Greenwich Hospital is providing essential cardiac care to patients with strong results. An elective angioplasty program is a logical and cost-efficient extension of the existing diagnostic cardiac catheterization and primary angioplasty program infrastructure, and would be

performed by many of the same expert physicians and staff, and in the same dedicated laboratories, as the existing programs.

c. Identify the Standard of Practice Guidelines that will be utilized in relation to the proposal. Attach copies of relevant sections and briefly describe how the Applicant proposes to meet each of the guidelines.

American College of Cardiology - Please see Attachment VI for the 2011 ACC/AHA/SCAI Guidelines and the 2007 SCAI Expert Consensus Document.

Quality and safety standards for the elective angioplasty program are paramount. As with the primary angioplasty program, the Hospital will continue to be part of the Yale-New Haven Heart and Vascular Center and will continue to draw on the collective clinical resources and experience of the Center and comply with all standards, protocols, policies, procedures and quality assessments. Yale-New Haven Heart and Vascular Center staff will continue to provide clinical oversight, educational training and quality review services to ensure high quality outcomes. The medical direction for the program will continue to be provided by the appointed YSM interventional cardiologist. All of this ensures one standard of care across the Yale New Haven Health System and the highest possible angioplasty care provided at Greenwich Hospital. The clinical experience gained from the additional volume of the elective angioplasty program will serve to further improve the clinical competency of the program staff.

Greenwich Hospital will meet the guidelines through clinical policies and procedures, medical staff credentialing and quality assurance processes. In addition, it is important to note that the interventional cardiology clinical faculty from the Yale School of Medicine, who will perform the majority of elective angioplasty procedures at Greenwich Hospital, are highly skilled with considerable experience in this procedure. At the various sites where these physicians practice (including Yale-New Haven Hospital, Greenwich Hospital, the West Haven VA and Lawrence & Memorial Hospital), they performed more than the guideline recommended procedures in Fiscal Year 2011.

5. Organizational and Financial Information

a. Identify the Applicant's ownership type(s) (e.g. Corporation, PC, LLC, etc.).

The ownership type is Corporation.

b. Does the Applicant have non-profit status?

☒ Yes (Provide documentation) ☐ No

Please see Attachment XIII for documentation of non-profit status.

c. Provide a copy of the State of Connecticut, Department of Public Health license(s) currently

held by the Applicant and indicate any additional licensure categories being sought in relation to the proposal.

Please see Attachment XIV for copies of licenses.

d. Financial Statements

i. If the Applicant is a Connecticut hospital: Pursuant to Section 19a-644, C.G.S., each hospital licensed by the Department of Public Health is required to file with OHCA copies of the hospital's audited financial statements. If the hospital has filed its most recently completed fiscal year audited financial statements, the hospital may reference that filing for this proposal.

Copies of both YNHH's and GH's audited financial statements for FY 2010 are currently on file with OHCA.

ii. If the Applicant is not a Connecticut hospital (other health care facilities): Audited financial statements for the most recently completed fiscal year. If audited financial statements do not exist, in lieu of audited financial statements, provide other financial documentation (e.g. unaudited balance sheet, statement of operations, tax return, or other set of books.)
Not applicable.

e. Submit a final version of all capital expenditures/costs as follows:

Table 2: Proposed Capital Expenditures/Costs

Medical Equipment Purchase	**$ 0**
Imaging Equipment Purchase	
Non-Medical Equipment Purchase	
Land/Building Purchase *	
Construction/Renovation **	
Other Non-Construction (Specify)	
Total Capital Expenditure (TCE)	**$ 0**
Medical Equipment Lease (Fair Market Value) ***	
Imaging Equipment Lease (Fair Market Value) ***	
Non-Medical Equipment Lease (Fair Market Value) ***	
Fair Market Value of Space ***	
Total Capital Cost (TCC)	**$ 0**
Total Project Cost (TCE + TCC)	**$ 0**
Capitalized Financing Costs (Informational Purpose Only)	
Total Capital Expenditure with Cap. Fin. Costs	**$ 0**

* If the proposal involves a land/building purchase, attach a real estate property appraisal including the amount; the useful life of the building; and a schedule of depreciation.
** If the proposal involves construction/renovations, attach a description of the proposed building work, including the gross square feet; existing and proposed floor plans; commencement date for the construction/
*** If the proposal involves a capital or operating equipment lease and/or purchase, attach a vendor quote or invoice; schedule of depreciation; useful life of the equipment; and anticipated residual value at the end of the lease or loan term.

Not applicable. There are no capital costs associated with the proposal.

f. List all funding or financing sources for the proposal and the dollar amount of each. Provide applicable details such as interest rate; term; monthly payment; pledges and funds received to date; letter of interest or approval from a lending institution.

Not applicable. The proposal does not include any incremental capital costs; therefore, no funding or financing is required.

g. Demonstrate how this proposal will affect the financial strength of the state's health care system.

This proposal will result in lower costs resulting from a decrease in patient transfers and a second procedure for some patients. Through the fuller use of its existing angioplasty infrastructure at Greenwich Hospital, including physicians and staff, more efficient care and enhanced patient quality and safety will result. The facility, physicians, staff and equipment required to provide elective angioplasty services are already in place at Greenwich Hospital.

6. Patient Population Mix: Current and Projected

a. Provide the current and projected patient population mix (based on the number of patients, not based on revenue) with the CON proposal for the proposed program.

Table 3: Patient Population Mix

	Current** FY ***	Year 1 FY ***	Year 2 FY ***	Year 3 FY ***
Medicare*	40.5%	40.5%	40.5%	40.5%
Medicaid*	5.4%	5.4%	5.4%	5.4%
CHAMPUS & TriCare				
Total Government	**45.9%**	**45.9%**	**45.9%**	**45.9%**
Commercial Insurers*	48.7%	48.7%	48.7%	48.7%
Uninsured	5.4%	5.4%	5.4%	5.4%
Workers Compensation				
Total Non-Government	**54.1%**	**54.1%**	**54.1%**	**54.1%**
Total Payer Mix	**100.0%**	**100.0%**	**100.0%**	**100.0%**

* Includes managed care activity.
** New programs may leave the "current" column blank.
*** Fill in years. Ensure the period covered by this table corresponds to the period covered in the projections provided.

b. Provide the basis for/assumptions used to project the patient population mix.

The current population mix for the current cases performed at the hospital was utilized in the projections.

7. Financial Attachments I & II

a. Provide a summary of revenue, expense, and volume statistics, without the CON project, incremental to the CON project, and with the CON project. **Complete Financial Attachment I.** (Note that the actual results for the fiscal year reported in the first column must agree with the Applicant's audited financial statements.) The projections must include the first three full fiscal years of the project.

Please see Attachment XV.

b. Provide a three year projection of incremental revenue, expense, and volume statistics attributable to the proposal by payer. **Complete Financial Attachment II.** The projections must include the first three full fiscal years of the project.

Please see Attachment XVI.

c. Provide the assumptions utilized in developing **both Financial Attachments I and II** (e.g., full-time equivalents, volume statistics, other expenses, revenue and expense % increases, project commencement of operation date, etc.).

Please see Attachment XVII.

d. Provide documentation or the basis to support the proposed rates for each of the FYs as reported in Financial Attachment II. Provide a copy of the rate schedule for the proposed service(s).

Rates for the proposed service will be approximately the same as the current service.

e. Provide the minimum number of units required to show an incremental gain from operations for each fiscal year.

Each additional incremental case produces an incremental gain.

f. Explain any projected incremental losses from operations contained in the financial projections that result from the implementation and operation of the CON proposal.

No incremental losses from operations are anticipated.

g. Describe how this proposal is cost effective.

The proposed elective angioplasty program maximizes use of the existing high-cost infrastructure of the primary angioplasty program and permits existing and available highly qualified expert physicians and staff to perform both primary and elective angioplasties for which they have been trained and are qualified to perform. In addition, as noted above, through System-wide integration, coordination of care practices and standardization, more cost effectiveness and evidence-based care will be provided.

Elective angioplasty patients can fare well in experienced hospitals with no heart surgery capabilities

American Heart Association Late-Breaking Clinical Trial Report - Abstract: 18558 - EMBARGOED UNTIL 8AM ET November 14, 2011

Study Highlights:

- Patients who had non-emergency artery-opening angioplasty or stent implantation at hospitals without heart surgery capabilities fared as well as those in hospitals that did.
- Both groups of patients had less than a 1 percent death rate.

ORLANDO, FLA., Nov. 14, 2011 — Patients who had non-emergency artery-opening angioplasty or stent implantation at experienced hospitals without on-site heart surgery capabilities fared no worse than those in surgery-equipped hospitals, according to late-breaking research presented at the American Heart Association's Scientific Sessions 2011.

In a study from the Cardiovascular Patient Outcomes Research Team (CPORT), researchers randomly assigned 13,995 patients to have their procedure done at a hospital with cardiac surgery capabilities and 4,523 patients at hospitals without.

The death rate after six weeks was almost the same for each group — just under 1 percent, researchers said. Furthermore, neither group were more likely to need emergency heart bypass surgery.

If emergency surgery was required at a hospital without on-site surgery, the patient was transferred urgently.

The American College of Cardiology Foundation/American Heart Association guidelines have recommended that elective angioplasty and stent implantation be done at hospitals with cardiac surgery facilities in the same building in case emergency surgery is needed.

In this study, emergency surgery was needed for 20 of the 13,995 patients undergoing procedures at hospitals without on-site surgery and 10 of the 4,523 patients treated at hospitals with surgery available.

However, the need for emergency surgery during these procedures has plummeted over the last few decades, said Thomas Aversano, M.D., the study's lead researcher and associate professor of medicine at Johns Hopkins Medical Institutions in Baltimore, Md.

"In the 1980s, the need for cardiac surgery was high; 5 percent to 7 percent of these cases could require emergency open heart or bypass surgery," Aversano said. "The cardiac operating room was kept open in the event a complication requiring surgery occurred. Now it's one in 500 or one in 1,000. It's very uncommon."

In this carefully structured study, the 60 hospitals without cardiac surgery capabilities had to be able to annually perform at least 200 angioplasties or stent implantations, also called percutaneous coronary interventions or PCI. The physicians doing the procedures were required to be performing more than 75 PCI cases annually. All centers underwent a formally developed PCI program.

Some states restrict hospitals from performing these procedures without on-site surgery, except for an emergency, Aversano said.

"We do not support the spread of angioplasty to every hospital in the United States," he said. "However, it can be burdensome and costly for all medical centers to have cardiac surgery capabilities. And it doesn't make sense to create more surgical programs just to support the angioplasty programs."

He said regional healthcare planners can use the data from the study to make informed decisions about which hospitals should have PCI capability, with the aim of improving quality, improving access and lowering costs.

The study provides only short-term results, but early next year, researchers will have data revealing how patients fared nine months after the procedure. They said this will be important in assessing the overall effect of these two systems of care on ultimate patient outcomes.

Co-authors are the C-PORT investigators.

American Journal of Therapeutics
Outcomes of Nonemergent Percutaneous Coronary Intervention With and Without On-site Surgical Backup: A Meta-Analysis

American Journal of Therapeutics 18, e22–e28 (2011)

Outcomes of Nonemergent Percutaneous Coronary Intervention With and Without On-site Surgical Backup: A Meta-Analysis

Param Puneet Singh, MD,* Mukesh Singh, MD, Updesh Singh Bedi, MD, Sasikanth Adigopula, MD, Sarabjeet Singh, MD, Vamsi Kodumuri, MD, Janos Molnar, MD, Aziz Ahmed, MD, Rohit Arora, MD, and Sandeep Khosla, MD

Despite major advances in percutaneous coronary intervention (PCI) techniques, the current guidelines recommend against elective PCI at hospitals without on-site cardiac surgery backup. Nonetheless, an increasing number of hospitals without on-site cardiac surgery in the United States have developed programs for elective PCI. Studies evaluating outcome in this setting have yielded mixed results, leaving the question unanswered. Hence, a meta-analysis comparing outcomes of nonemergent PCI in hospitals with and without on-site surgical backup was performed. A systematic review of literature identified four studies involving 6817 patients. Three clinical end points were extracted from each study and included in-hospital death, myocardial infarction, and the need for emergency coronary artery bypass grafting. The studies were homogenous for each outcome studied. Therefore, the combined relative risks (RRs) across all the studies and the 95% confidence intervals (CIs) were computed using the Mantel-Haenszel fixed-effect model. A two-sided alpha error less than 0.05 was considered to be statistically significant. Compared with facilities with on-site surgical backup, the risk of in-hospital death (RR, 2.7; CI, 0.6–12.9; $P = 0.18$), nonfatal myocardial infarction (RR, 1.3; CI, 0.7– 2.2; $P = 0.29$), and need of emergent coronary artery bypass grafting (RR, 0.46; CI, 0.06– 3.1; $P = 0.43$) was similar in those lacking on-site surgical backup. The present meta-analysis suggests that there is no difference in the outcome with regard to risk of nonfatal myocardial infarction, need for emergency coronary artery bypass grafting, and the risk of death in patients undergoing elective PCI in hospitals with and without on-site cardiac surgery backup.

Keywords: onsite backup surgery, percutaneous coronary intervention

INTRODUCTION

Percutaneous coronary interventions (PCI) were introduced for the first time in 1977 by Andreas Gruntzig.[1] Since then, many technologic and pharmacologic advances in PCI have been made. Steerable guidewires, coronary artery stents,[2] and new antiplatelet therapies have improved the success rate of PCI procedures and significantly reduced the risk of per-procedural complications needing urgent cardiac surgery. Recent studies have shown that the need for emergency cardiac surgery is now as low as 0.3% to 0.6%.[2,3] As a result, the number of procedures has increased worldwide,[4] and an increasing proportion of procedures are performed at centers without surgical backup.[5,6] Despite major advances in PCI technique, the current American College of Cardiology/American Heart Association/-Society of Cardiovascular Angiography and Intervention 2005 guidelines[7] for PCI recommend against elective PCI at hospitals without on-site cardiac surgery (Class III indication). Acknowledging this trend, the Society for Cardiovascular Angiography and Interventions recently issued an expert consensus statement that provides practice standards for elective PCI at hospitals

without on-site cardiac surgery.[8] Because of the conflicting literature on this subject, the question about safety of elective PCI at centers without surgical backup remains unanswered. Hence, a meta-analysis comparing outcomes of nonemergent or elective PCI in hospitals with and without on-site surgical backup was performed.

METHODS

We performed this review in accordance with the Quality of Reporting of Meta-analysis statement and the Consolidated Standards of Reporting Trials Group recommendations.[9]

Literature search

A systematic review of the medical literature was performed to identify studies evaluating the efficacy or adverse outcomes of combination therapy in patients with congestive heart failure, acute myocardial infarction, or high-risk diabetes mellitus. Eligible studies were identified by searching MEDLINE (January 1966–December 2008), EMBASE (January 1980–December 2006), the Cochrane Library (Controlled Trials Register and Database of Systematic Reviews, all years), the National Institute of Health Clinical Trials (http://www.clinicaltrials.gov), and the U.S. Food and Drug Administration web sites (http://www.FDA.gov) and relevant bibliographies.

Study selection

There was a written protocol with explicit inclusion and exclusion criteria, which was followed for all articles that were screened. All titles and abstracts from the results of our computerized search were reviewed by the authors for potential inclusion in our study. We also searched for relevant review articles and their bibliographies for articles. In addition to our computerized search, we manually reviewed the reference list of all retrieved articles to complete our search for randomized, controlled trials comparing outcome of PCI with and without surgical backup. Study selection process is outlined in Figure 1.

Studies were excluded if they did not meet the inclusion criteria. Those studies that were not done in human subjects, not randomized, published in nonpeer-reviewed journals, or with inadequate follow up were excluded from our analysis.

End points and definitions

Three clinical end points were extracted from each study and included: in-hospital death, nonfatal myocardial infarction (MI), and need for emergency coronary artery bypass surgery (CABG). End point definitions were those used in the individual trials. Death was defined as in-hospital mortality from any cause. MI was defined as enzymatic and electrocardiographic changes consistent with MI. Emergency CABG surgery was defined as unplanned surgical revascularization within 48 hours of PCI. All end points were assessed at the end of follow up of the trial.

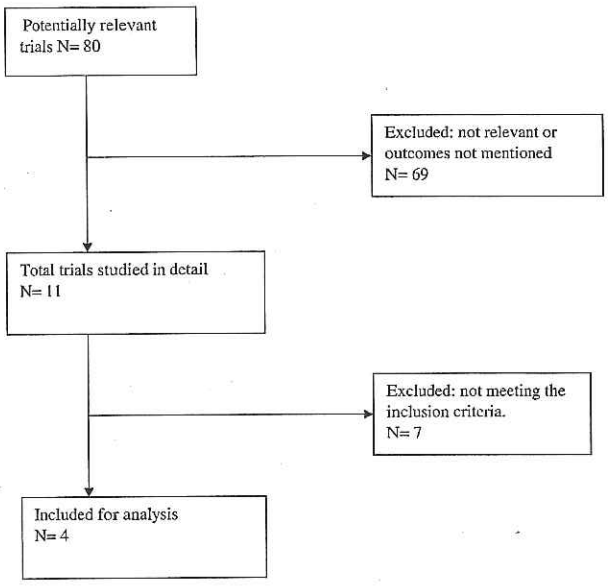

FIGURE 1. Trial selection and inclusion flow diagram.

Data extraction

The two authors (PS, MS) independently screened the titles and abstracts for eligibility. Full articles were retrieved for all titles for which abstracts were not available and for all abstracts that appeared to potentially fulfill the inclusion and exclusion criteria. It was decided that if there was a conflict between the two authors, then the study in question would be brought to the panel of all authors where the decision would be made for its inclusion. Data extraction was done independently by two authors. Each author tabulated important trial characteristics and assessed methodological quality (jaded score), including patient demographics such as age, study population, sample size diabetes, hypertension, and angiographic characteristics.

Statistical analysis

The statistical analysis was performed with the Comprehensive Meta-Analysis software package (Version CM 2.2; Biostat, Englewood, NJ). We calculated odds ratio for each study outcome to allow for pooling of similar outcomes. All the results are reported as the pooled odds ratio with 95% confidence interval (CI). Chi square test

Table 1. Results of heterogeneity analysis.

End Point	Q-value	df (Q)	*P* Value	I-squared	Result
In-hospital death	3.4	1	0.067	70.2	Homogenous
Nonfatal myocardial infarction	1.4	3	0.707	0.0	Homogenous
Emergency coronary artery bypass graft	2.0	1	0.155	50.7	Homogenous

was used to assess heterogeneity. The studies were homogenous for each outcome studied (Table 1). Therefore, the combined relative risks (RRs) across all the studies and the 95% CIs were computed using the Mantel-Haenszel fixed-effect model. A two-sided alpha error less than 0.05 was considered to be statistically significant.

Role of funding source

The funding source had no role in the design, conduct, or reporting of the study or in the decision to submit the manuscript for publication.

RESULTS

Data synthesis and study characteristics

Figure 1 represents the trial selection and inclusion flow diagram. After the initial search based as described previously, a total of 80 articles was considered as potentially relevant. After the title and abstract review, 69 of the 80 were excluded because they were not randomized, non-English trials, or did not meet our inclusion criteria. From the remaining 11, seven were excluded after full text review because there was inadequate follow up, the outcomes measured were different, or the study characteristics did not meet our inclusion criteria. Our search of abstracts from conference proceedings of the American College of Cardiology, American Heart Association, European Society of Cardiology, and Heart Failure Society of America did not reveal any additional studies that satisfied our inclusion and exclusion criteria. Our meta-analysis included the remaining four randomized, controlled trials involving 6817 patients.[10–13]

Baseline characteristics

Table 2 summarizes the study population characteristics of all the studies included for the analysis. All four studies were large randomized, controlled trials with adequate follow up. Mean duration of follow up was 31 months. Mean age of patients enrolled was 64 years. Allocation sequence generation and concealment were adequately described in all four studies. All the studies had two arms comparing the outcome of patients undergoing elective PCI at two centers with and without on-site cardiac surgery backup. In-hospital death and need for emergency surgery as outcomes were reported in two studies,[12,13] whereas non-fatal MI was reported in all four studies included in this meta-analysis.[10–13]

Clinical outcomes

Angiographic characteristics of patients in the included studies are given in Table 3. The outcomes measured in our analysis were in-hospital death, nonfatal MI, and need for emergent CABG.

In-Hospital Death

Compared with hospitals with surgical capability, there was no difference in the risk of in-hospital death in patients undergoing elective PCI at centers without surgical back up (RR, 2.7; CI, 0.6–12.9; $P = 0.18$) (Fig. 2).

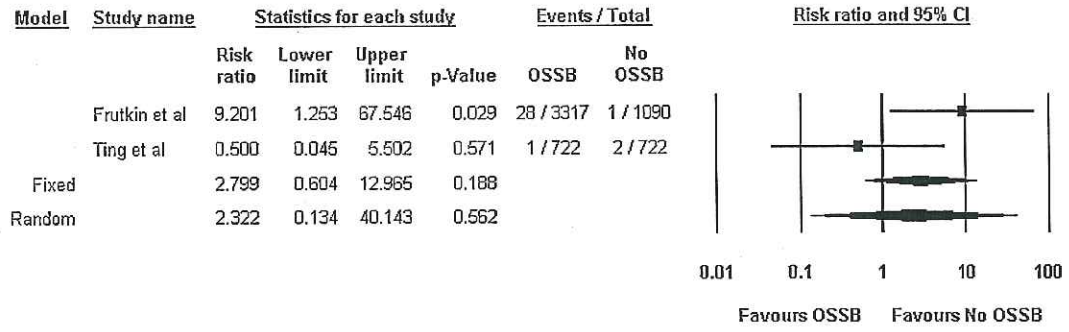

FIGURE 2. Risk of in-hospital death with on-site surgical backup versus no backup.

LVEF less than 40%	SB	—	—	374 (19%)	92 (13%)
	NSB	—	—	59 (9%)	74 (10%)

MI, myocardial infarction; PCI, percutaneous coronary intervention; TIA, transient ischemic attack; CABG, coronary artery bypass grafting; PVD, peripheral vascular disease; DM, diabetes mellitus; HTN, hypertension; CKD, chronic kidney disease; CHF, congestive heart failure; LVEF, left ventricular ejection fraction; SB, on-site surgical backup group; NSB, no on-site surgical backup group.

Nonfatal Myocardial Infarction

The risk of nonfatal MI was similar in both groups of patients without any significant difference (RR, 1.3; CI, 0.7–2.2; $P = 0.29$) (Fig. 3).

Need for Emergent Coronary Artery Bypass Grafting

The risk for need for emergent CABG did not differ between the patients undergoing PCI at centers with and without surgical backup (RR, 0.46; CI, 0.06–3.1; $P = 0.43$) (Fig. 4).

DISCUSSION

Our meta-analysis shows that there is no difference in the incidence of in-hospital mortality, nonfatal MI, and

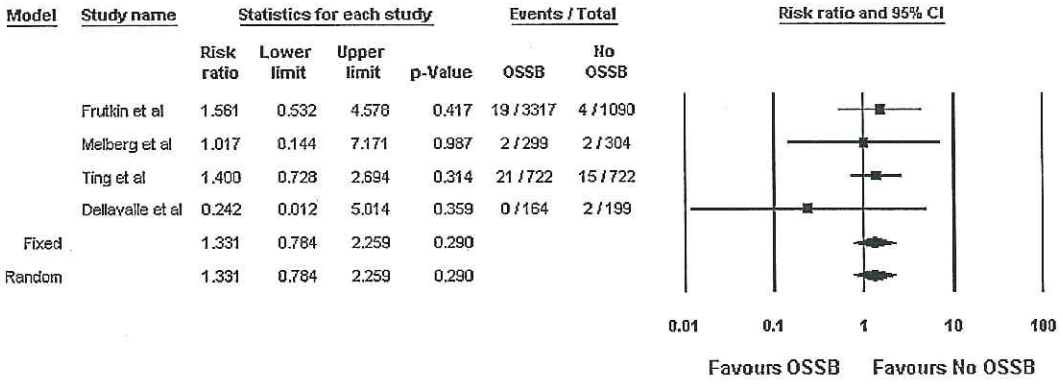

FIGURE 3. Risk of nonfatal myocardial infarction with on-site surgical backup versus no backup.

the need for emergency CABG in patients undergoing PCI at centers with and without surgical backup (Fig. 5). Overall, of 6817 patients in all four studies, total in-hospital deaths were 32 (0.47%). In the group with no surgical backup, in-hospital mortality was 0.13% (three of 2315 patients died), whereas in the group with on-site surgical backup, the in-hospital mortality rate was 0.6% (29 of 4502 patients died).

The purpose of cardiac surgical backup for PCI is to provide emergent hemodynamic support and revascularization to salvage complications that cannot be addressed by catheter-based techniques. PCI can be complicated by life-threatening hemodynamic and ischemic emergencies that can be addressed only by the availability of emergency cardiac surgery. The role of on-site cardiac surgical backup is twofold: on-site cardiac surgical backup provides prompt availability of cardiac surgical support in the event of a hemodynamic or ischemic emergency and on-site cardiac surgical backup is a surrogate for an institution's overall capability to provide a highly experienced and promptly available team to respond to a catheterization laboratory emergency.[14] Technical improvements in PCI instruments and techniques have led to the concept that the requirement for emergency cardiac surgery is sufficiently rare that PCI can be performed safely without on-site surgery. This has led to the development of elective angioplasty programs without on-site surgical coverage.

Cardiac surgical backup for PCI has evolved from a formal surgical standby in the 1980s to an informal arrangement of first-available operating room and, in some cases, off-site surgical backup.[15–21] With the advent of intracoronary stenting, there has been a decrease in the need for emergency CABG ranging between 0.4% and 2%.[2,3,21–28] Not surprisingly, emergency CABG surgery for a patient with an occluded or dissected coronary artery is associated with a higher mortality than elective surgery.[21,29–34] Emergency procedures are also associated with high rates of perioperative infarction and less frequent use of

arterial conduits. Complex coronary artery disease intervention, hemodynamic instability, and prolonged time to reperfusion are contributing factors to the increased risk of emergency bypass surgery.

A recently published report from analysis of National Cardiovascular Data Registry showed findings similar to our meta-analysis. This National Cardiovascular Data Registry data analysis showed that off-site PCI centers had similar observed procedure success, morbidity, emergency cardiac surgery rates, and mortality in cases that required emergency surgery. The risk-adjusted mortality rates in off-site PCI facilities were comparable to those of PCI centers that had cardiac surgery on-site regardless of whether PCI was performed as primary therapy for ST-elevation MI or in a nonprimary setting.[35]

Like with any meta-analysis, our analysis has limitations inherent to such analysis. Meta-analyses have inherent methodological limitations in that summary data are pooled from studies of different designs. The study population used in all the trials, although being somewhat similar, is not exactly the same. Although we detected no significant heterogeneity, a meta-analysis cannot replace large, well-conducted randomized trials as evidence for and against an intervention.

Our meta-analysis adds to the current body of literature on PCI by considering between study heterogeneity, bias, consistency of outcomes among studies and inclusion of large recent studies. This meta-analysis shows that there is no difference in the outcome with regard to risk of nonfatal MI, need for emergency CABG, and the risk of death in patients undergoing elective PCI in hospitals with and without on-site cardiac surgery backup.

Brindis, MD, MPH,‖‖ on behalf of the National Cardiovascular Data Registry (NCDR)

Since the introduction of percutaneous coronary intervention (PCI) in 1977 by Andreas Gruntzig (1), the presence of cardiac surgery backup on site has been a recommended practice to treat the potential of life-threatening complications. As a result of major improvements in technology and pharmacology, the need for emergency cardiac surgery is now infrequent (0.3% to 0.6%) (2,3). Moreover, primary PCI has been accepted as superior to fibrinolytic therapy for ST-segment elevation myocardial infarction (STEMI) (4). These developments have provided the justification for some hospitals without cardiac surgery to develop PCI programs based on a strategy to provide more rapid care for STEMI (5,6) and to increase the availability of PCI to patients in geographically underserved areas.

Favorable outcomes for primary PCI performed in facilities without cardiac surgery backup on site have been reported (7–9). In addition, smaller observational studies have extended this concept to both primary and elective PCI (10–14), and even PCI limited to elective cases (15). However, there are few large studies that have directly compared the procedural outcomes of both primary and elective PCI at facilities without cardiac surgery on site with those that have traditional surgery on site (16–18). Because of the conflicting literature on this subject, the American College of Cardiology (ACC), American Heart Association (AHA), and Society for Cardiovascular Angiography and Interventions (SCAI) 2005 PCI guidelines continue to designate primary PCI a Class IIb indication (may be considered), and elective PCI a Class III indication (not recommended) when performed at facilities without surgical backup on site (19). The 2007 PCI guideline focused update did not address or change these designations (20). Despite

From the *Wake Forest University School of Medicine, Winston-Salem, North Carolina; †Rush-Presbyterian-St. Luke's Medical Center, Chicago, Illinois; ‡Duke Clinical Research Institute, Durham, North Carolina; §Exeter Hospital, Exeter, New Hampshire; ‖Texas A&M University College of Medicine, Scott & White HealthCare, Temple, Texas; ¶Mayo Clinic, Rochester, Minnesota; #University of Texas Health Science Center, Houston, Texas; **Denver VA Medical Center, Denver, Colorado; ††Christiana Health Care System, Newark, Delaware; ‡‡Sutter Pacific Heart Centers, San Francisco, California; §§National Cardiovascular Data Registry, Washington, DC; and ‖‖Northern California Kaiser Permanente, San Francisco, California. Data analysis was performed by the Duke Clinical Research Institute with funding from the National Cardiovascular Data Registry. Drs. Kutcher and Klein perform percutaneous coronary intervention (PCI) at facilities that have on-site cardiac surgery. Dr. Wharton is a consultant to Corazon, The Heart and Vascular Experts, and performs PCI at a facility that does not have on-site cardiac surgery. Dr. Dehmer is Chief, Division of Cardiology, Texas A&M College of Medicine, Scott & White HealthCare, which includes facilities that have on-site cardiac surgery and facilities that do not. Dr. Singh performs PCI at Mayo Clinic facilities that have on-site cardiac surgery and facilities that do not. Dr. Anderson performs PCI at a facility that has on-site cardiac surgery.

these classifications, the number of PCI programs in the U.S. without surgery on site has increased significantly over the past several years (21). Recently, a SCAI expert panel outlined practical consensus principles for PCI performed at facilities without surgery on site, while not specifically encouraging or endorsing this practice (22).

The National Cardiovascular Data Registry (NCDR) was established by the ACC to proactively monitor and assess the clinical practice of cardiology in the U.S. (23). The NCDR CathPCI Registry, cosponsored by the ACC and SCAI, offers its participant institutions data field definitions, uniform data entry, secure transmission requirements, a data quality program, and risk-adjustment algorithms (24–26). Therefore, this registry provides an excellent resource of comparative data, in a relative contemporary clinical setting, to address the controversy over PCI at facilities without surgical backup on site.

Abbreviations and Acronyms

ACC = American College of Cardiology
AHA = American Heart Association
CABG = coronary artery bypass graft surgery
IABP = intra-aortic balloon pump
MI = myocardial infarction
NSTEMI = non–ST-segment myocardial infarction
PCI = percutaneous coronary intervention
SCAI = Society for Cardiovascular Angiography and Interventions
STEMI = ST-segment elevation myocardial infarction

Methods

Study population. Clinical characteristics and in-hospital outcomes were assessed in consecutive PCI cases reported to the NCDR CathPCI Registry from January 1, 2004, to March 30, 2006. Standardized NCDR version 3.04 definitions and data fields were used by all participating sites (27). The analysis cohort consisted of 308,161 patients from 465 PCI-capable facilities. Of these, 8,736 patients had PCI performed at 60 institutions in which it was verified there was no surgical backup on site within the buildings or campus that constituted the facility (off-site facility). The remaining 299,425 patients underwent PCI at 405 facilities that had cardiac surgery on site (on-site facility). Off-site PCI facilities comprised 13% of sites and 3% of patients in the NCDR CathPCI Registry during the study period.

Definitions. The primary outcomes for analysis were the incidence of emergency surgery and in-hospital death from all causes after PCI. Emergency surgery was defined as coronary artery bypass graft (CABG) surgery performed after PCI in which there was evidence of active ischemia or mechanical dysfunction (emergency), or if the patient required cardiopulmonary resuscitation en route to the operating room or before anesthesia (emergent/salvage). Secondary outcomes included procedure success, total complications (any general, bleeding, or vascular complications), and reperfusion time in cases of primary PCI for STEMI.

Off-site data clarification. During initial analysis, variations in 2 data fields unique to off-site PCI programs were noted. The field "CABG during this admission" permitted entry of only 1 category. In off-site centers, there was a disproportionately low incidence of "emergency" surgery, but a proportionately large number of patients "transferred for CABG" entered in this field. In addition, "transfer" patients could be counted as "alive" in the data field "discharge status" from an off-site center, but this opened the potential that a subsequent death after emergency surgery at the outside surgical center may not have been captured.

To resolve these issues, we conducted a data clarification project. Off-site centers with specific data points in question were queried to clarify whether a "transfer for CABG" data point was for elective or emergency surgery, and to verify the eventual survival at the off-site surgical center. This effort also provided an opportunity to gather additional information by a Capabilities Survey to reaffirm a true off-site status and to assess organization, staffing, and logistics. All of the off-site programs were invited to fill out the survey form, even those sites in which data clarification was not necessary.

Of the 8,736 patients undergoing PCI in off-site centers, 172 (2%) patients from 43 sites required data clarification regarding transfer surgery or mortality status. Of these 43 sites, 38 (88%) sites were able to clarify CABG status and/or mortality information for 154 of the 172 (90%) patients. For the 18 patients (0.2% of 8,736) whose transfer or mortality data were not clarified, if CABG status was uncertain, the original record entry was used for the CABG status-related analysis. If the subsequent mortality at the receiving surgery center could not be clarified, these patients were not included in the analysis of observed or risk-adjusted mortality.

Statistical analysis. Data analysis was performed by the Duke Clinical Research Institute. For descriptive analyses, institutional comparisons between off- and on-site PCI centers were made based on hospital characteristics. Comparisons between patients were made based on clinical characteristics, treatment profiles, procedural details, and clinical outcomes. These aggregates were further divided and analysis performed in patients who underwent primary PCI as first-line therapy for reperfusion in the presence of STEMI, and to the remainder of patients who underwent PCI in a nonprimary setting. Continuous variables are presented as mean with SD or as frequencies with percentages in each pre-specified category. Categorical variables are expressed as frequencies with percentages. To test for independence of patients' baseline characteristics, in-hospital care patterns and outcomes with respect to off-site versus on-site centers, the Wilcoxon rank-sum test was used for continuous variables, and the Pearson chi-square test was used for categorical variables.

A multivariable logistic regression model was then used to estimate the risk-adjusted association between on-site versus off-site PCI center surgical status and primary outcomes. Variables adjusted to mortality in-

cluded age, sex, insulin-treated diabetes mellitus, hypercholesterolemia, hypertension, dialysis, cerebrovascular disease, chronic lung disease, peripheral vascular disease, congestive heart failure, prior CABG, prior PCI, prior myocardial infarction (MI), cardiogenic shock at presentation, MI status (STEMI, non–ST-segment myocardial infarction [NSTEMI], and no MI), pre-operative intra-aortic balloon pump (IABP), PCI status (rescue, emergent, urgent, and elective), subacute thrombosis in a major artery, any treated lesion in left main artery, any treated lesion with pre-procedure stenosis 100%, any treated lesion with pre-procedure Thrombolysis In Myocardial Infarction (TIMI) flow grade 0, any treated lesion with high/C risk characteristics (see definition, bottom legend, Table 1), and total number of lesions treated. Variables adjusted to emergency CABG included cardiogenic shock, MI status (STEMI, NSTEMI, and no MI), pre-operative IABP, PCI status (rescue, emergent, urgent, and elective), and any treated left main artery lesion.

The Generalized Estimate Equation method (28) was applied to account for within-hospital clustering, considering patients at the same hospital are more likely to have similar responses relative to patients in other hospitals (i.e., within-center correlation for response). This method produces estimates comparable to those from ordinary logistic regression, but estimated variances are adjusted for the correlation of outcomes within each hospital.

Because not all off-site PCI center patient mortality data could be clarified, a sensitivity analysis was performed. This analysis utilized the same multivariable logistic regression model but imputed data to either of the following: patients with missing mortality data were considered either as all had died (worst scenario) or as all were alive (best scenario) on discharge.

Results

Institutional characteristics. Institutional characteristics are shown in Table 2. Compared with on-site centers, off-site PCI facilities had smaller bed capacity, were more likely to be located in nonurban areas, and had lower annual total PCI and primary PCI volume ($p < 0.001$). Overall, 43 (72%) of the off-site programs performed <200 total PCIs per year, and only 3 sites (5%) had >400 cases, suggesting that it was unlikely the outcomes were preferentially influenced by a few large-volume centers. The recommended volume standard of 36 or more primary PCIs per year (19) was achieved by 42% of the off-site programs compared with 80% of the on-site centers ($p < 0.001$).

Off-site capabilities survey. The survey (Table 3) was completed by 53 of the 60 off-site PCI facilities (88%). Approximately one-quarter of the centers had travel distances >40 miles and transit times (estimated driving or flight) >30 min. This information also reaffirmed that these were true off-site programs and did not have surgery back-up nearby in the next building. Full 24-h, 7-day coverage for PCI was provided by 92% of the sites. Both primary and elective PCI were performed in 79% of the centers, and none of the programs performed only elective PCI. Descriptive demographics regarding the organization of technical staff, interventional cardiologists, and transpor-

Data are n (%) unless otherwise indicated. *14 patients not included due to missing value for variable "Acute PCI." †High risk C lesion includes any of the following: diffuse (length >20 mm), excessive tortuosity of proximal segment, extremely angulated segments >90 degrees, total occlusions >3 months old and/or bridging collaterals, inability to protect major side branches, and degenerated vein grafts with friable lesions.

CABG = coronary artery bypass grafting; CHF = congestive heart failure; MI = myocardial infarction; PCI = percutaneous coronary intervention; SVG = saphenous vein graft.

tation modalities are further outlined in Table 3. Of note, 81% of the off-site programs reported that their interventional operators also rotated and performed PCI at on-site facilities.

Clinical characteristics. Clinical characteristics are shown in Table 1. In aggregate, on-site PCI centers generally treated patients with more risk factors and performed a greater percentage of PCI in multiple-lesion (33% vs. 29%, $p < 0.001$), saphenous vein graft (7% vs. 5%, $p < 0.001$), and higher lesion-risk cases (41% vs. 39%, $p = 0.001$). This difference was more pronounced in patients who underwent nonprimary PCI. In contrast, off-site facilities had a greater incidence of patients who had a clinical presentation of STEMI or NSTEMI (41% vs. 29%, $p < 0.001$) (Fig. 1).

Observed unadjusted procedural outcomes. Observed unadjusted procedural outcomes are shown in Table 4. Off-site facilities had slightly higher aggregate procedural success (94% vs. 93%, $p = 0.010$), predominantly due to higher success rates in nonprimary PCI cases. Aggregate total complications were similar in both off- and on-site facilities (6.5% vs. 6.3%), but off-site programs tended to have more bleeding events, and on-site more vascular complications. Off-site programs had fewer total complications in primary PCI (11.6% vs. 13.4%, $p = 0.029$) and had lower general (2.6% vs. 3.3%, $p = 0.001$) and vascular (0.8% vs. 1.1%, $p = 0.017$) complication rates in nonprimary PCI patients compared with on-site facilities.

In the overall PCI cohort, there was no significant difference in the incidence of emergency CABG surgery (0.3% vs. 0.4%, $p = 0.271$) or mortality with emergency CABG (13.6% vs. 12.8%, $p = 0.907$) between off- and on-site facilities, respectively. There was no difference in either of these variables when the analysis was stratified into primary PCI and nonprimary PCI patients. Although the unadjusted aggregate mortality rate was higher in off-site facilities (1.7% vs. 1.2%, $p < 0.001$) and appeared to be confined to patients who did not require emergency surgery, this difference did not persist when stratified by primary or nonprimary PCI. This increased unadjusted aggregate mortality was most likely due to a higher proportion of primary PCI patients (22% vs. 10%, $p < 0.001$) and STEMI and NSTEMI presentations (41% vs. 29%, $p < 0.001$) in off-site compared with on-site programs, respectively.

Primary PCI reperfusion times in nontransferred patients were significantly shorter in off-site PCI centers (mean 2.1 ± 5.1 h, median 1.4 h) compared with on-site (mean 2.6 ± 8.4 h, median 1.5 h, $p < 0.001$). These "reperfusion times" were defined as the time of arrival at the facility to the time of first treatment device deployment (27). Although both groups followed the same definition, these data were collected before there were major national quality

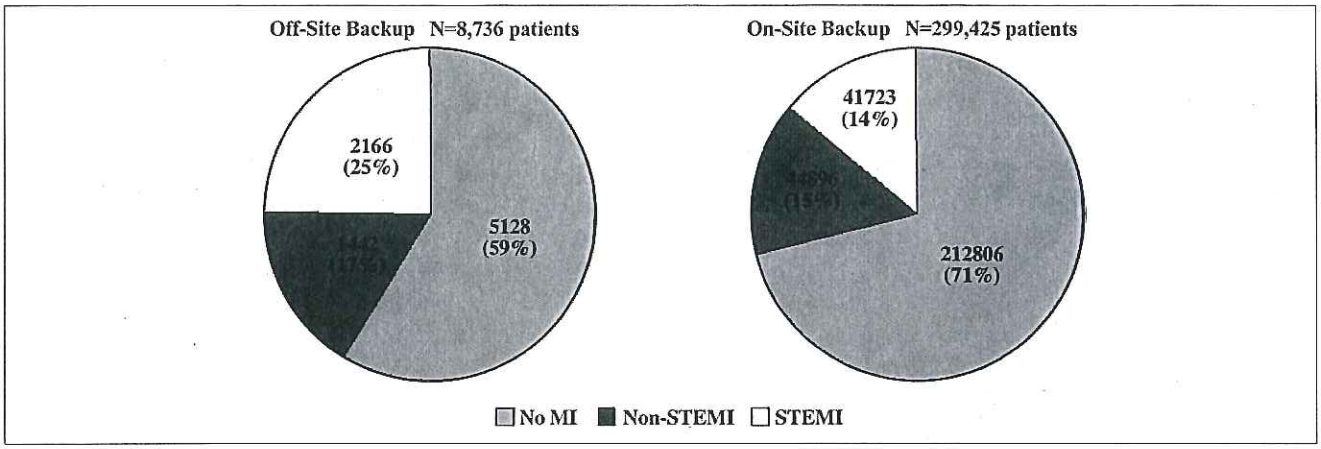
Figure 1 MI Presentation Status

Pie charts showing the relative distribution of myocardial infarction (MI) presentation within centers with on- or off-site surgical backup. **Blue areas** indicate no MI; **purple areas** indicate non–ST-segment elevation myocardial infarction (non-STEMI); **yellow areas** indicate STEMI. $p < 0.001$.



improvement initiatives and attention to the detailed measurements of true "door-to-balloon" times. Therefore, these times do not reflect the current door-to-balloon standards.

Risk-adjusted outcomes. After risk adjustment, there were no mortality differences between off- and on-site facilities among total PCI patients, primary PCI patients, nonprimary PCI patients, or patients who did not require emergency surgery (Fig. 2). There was a higher risk-adjusted odds of emergency surgery in on-site PCI centers (odds ratio: 0.60 [95% confidence interval: 0.37 to 0.98], $p = 0.042$).

A sensitivity analysis was performed comprising models that imputed missing mortality from off-site centers to 2 potential scenarios. Although the point estimate changed from 0.88 to 1.21, the confidence intervals surrounding these estimates were not statistically significant between off- and on-site facilities under either of these extreme assumptions.

Discussion

This study represents the largest and most comprehensive clinical comparison of PCI centers in the U.S. with and without cardiac surgery support on site. Despite lower annual PCI procedural volumes and more patients presenting with MI subsets, off-site PCI facilities reporting to the NCDR CathPCI Registry had similar rates of procedural success, morbidity, emergency surgery, and risk-adjusted mortality when compared with on-site PCI centers. These results persisted whether PCI was performed as primary therapy for STEMI or in a less urgent nonprimary PCI setting. In addition, the off-site Capabilities Survey in this study provided more descriptive information than has been previously reported in the literature regarding the organization and logistics of established off-site PCI programs.

It is important to contrast this study with the few large comparative reports in the literature. Wennberg et al. (16) found no difference in risk-adjusted mortality for primary PCI at facilities without surgery backup on site, but an increase in mortality for nonprimary/rescue PCI, particularly at very low-volume programs (<50 Medicare PCIs per year). Although their study had more hospitals without surgery on site (n = 178) and similar patient volumes (n = 8,168), the time period was from 1999 to 2001, and the data were derived from coded admission/discharge billing diagnoses confined to the Medicare population. In contrast, our study was based on well-defined contemporary clinical parameters and included clarification of ambiguous transfer data from the off-site PCI programs. We found no significant difference for risk-adjusted mortality between centers with and without surgery on site, in either primary or nonprimary PCI patients.

Ting et al. (17) previously reported comparable acute and long-term outcomes for both primary and elective PCI in a propensity score analysis of 1,007 cases from a PCI center without surgery on site matched to the same number of patients from a center with surgery on site. Of note, these Mayo Clinic facilities did not participate in the NCDR, and thus their patients were not included in our analysis.

Finally, in a recent report based on SCAAR (Swedish Coronary Angiography and Angioplasty Registry), Carlsson et al. (18) compared 8,838 PCI procedures from 14 PCI facilities that did not have cardiac surgery on site to 25,525 procedures from 10 PCI centers that did have surgery on site. Their analysis was adjusted for baseline variables, and demonstrated comparable 30-day and 1-year mortality and morbidity outcomes for both primary PCI and nonacute PCI. Although different variables were used in our risk-

Median				1.4	1.5				

Procedure success was defined as residual stenosis <50% with Thrombolysis In Myocardial Infarction flow grade 3 and minimal decrease in stenosis ≤20% in all lesions attempted. Total complications was defined as any of the following complications: general complications: periprocedural MI, cardiogenic shock, congestive heart failure, cerebrovascular accident, tamponade, thrombocytopenia, contrast reaction, renal failure; bleeding complications: bleeding at the access site, retroperitoneal, gastrointestinal, genitourinary, or other; vascular complications: access site occlusion, peripheral embolization, arterial dissection, arterial pseudoaneurysm, or arterio-venous fistula. Primary PCI was defined as PCI performed as first-line therapy for reperfusion in the presence of STEMI; does not include rescue or facilitated PCI or PCI for non-STEMI. Reperfusion time indicates time of arrival to facility to time of first intracoronary treatment device deployment. *14 patients not included due to missing value for variable "Acute PCI." †Clarified data.

Abbreviations as in Tables 1 and 2.

adjusted model, the in-hospital mortality/morbidity results are similar to these 2 studies.

The nonprimary PCI patient cohort in our study is not a reflection of purely elective PCI, as this group includes some patients who presented with acute coronary syndromes, NSTEMI, or after STEMI. However, the consideration of this group as "nonurgent" and a reasonable surrogate for elective PCI is consistent with the analyses done in the literature cited in the preceding text. In our study, the differentiation of patients in off-site versus on-site PCI centers into primary PCI and nonprimary PCI permitted a more comprehensive assessment and risk-adjustment analysis of the major clinical end points.

Within our study cohort, the aggregate incidence of emergency surgery was comparably low at off- and on-site PCI facilities (0.3% to 0.4%, respectively) and consistent with contemporary studies (2,3). When emergency surgery was necessary, the mortality rate was similarly high between off- (13.6%) and on-site (12.8%) facilities, and comparable to that reported in prior literature (2,3).

There have been concerns that off-site PCI facilities may tend to keep some borderline stable patients with suboptimal procedural results rather than initiate the logistics of emergency transfer to an outside surgical center. These patients may have adverse outcomes, as seems to be suggested by the aggregate unadjusted mortality rate in our study. However, in the risk-adjusted analyses, there was comparable in-hospital mortality for those off-site patients who were not transferred for emergency surgery.

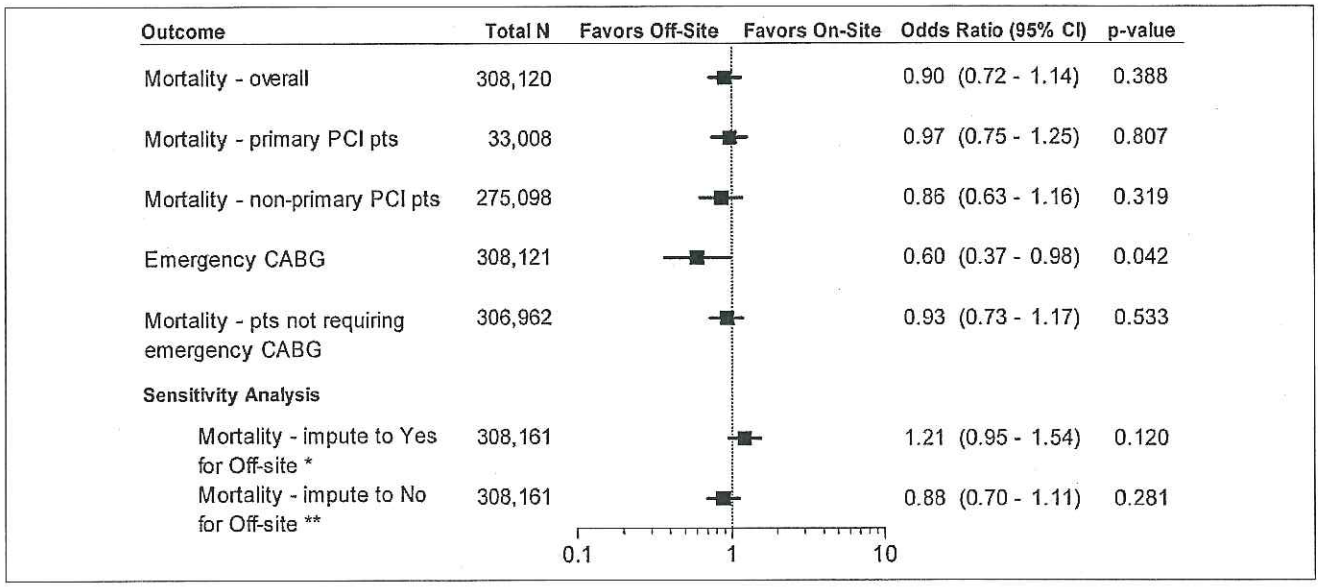
Conversely, the 1.5-fold higher risk-adjusted incidence of emergency surgery at on-site PCI centers could reflect a lower threshold to opt for emergency surgery if there is any doubt about a suboptimal result, as surgery is available without the added logistics of transfer. An alternative explanation could be that on-site centers perform higher risk elective cases, as is suggested by the clinical and lesion characteristics profiles in this study. In addition, it is possible that patients may have had initial angiography at off-site facilities, found to have complex coronary anatomy and/or high-risk MI subsets with a higher predisposition to emergency surgery, then deferred and transferred to an on-site center for PCI. These complicated potential scenarios and the detailed reasons for case selection were beyond the scope of the NCDR database elements. Regardless, the increased risk-adjusted incidence of emergency surgery at on-site PCI programs did not translate into an increase in mortality.

Data from the Capabilities Survey revealed a mean transit time of 25 ± 17 min from off-site facilities. The British Cardiovascular Interventional Society has recommended a 90 min to emergency surgery standard (29).

JACC Vol. 54, No. 1, 2009
June 30, 2009:16–24

Figure 2 Risk-Adjusted Analysis of Outcomes

Odds ratio plot of risk-adjusted outcomes, including sensitivity analysis for missing mortality data. Odds ratio: outcomes for patients at off-site (vs. on-site) facilities, adjusting for within site correlations and potential confounding variables. *Worst case scenario: all patients with missing mortality data were considered to have died. **Best case scenario: all patients with missing mortality data were considered as alive. CABG = coronary artery bypass graft surgery; CI = confidence interval; PCI = percutaneous coronary intervention; pts = patients.



This includes not only the transit time, but also the total time from the initial decision to transport (including call time, transfer of patient from catheterization laboratory to vehicle, vehicle to operating suite), to the actual time of initiating cardiopulmonary bypass at the receiving surgical center. The transit time in the NCDR survey was an estimate of basic travel time and did not include the above additional time elements. However, based on the transit time, most off-site PCI programs in our study may be able to meet this global standard of 90 min by having a clear decision process and heightened logistical coordination with ambulance services and the receiving surgical center.

The demographics of the off-site centers in our study suggests these facilities conform to the stated goals of lowering geographic barriers and facilitating access to PCI, particularly for those patients presenting with STEMI (5,6). The Capabilities Survey also indicates these programs are well staffed and organized with good logistical plans. The fact that 81% of the off-site center operators rotated to an on-site PCI center suggests that most of the off-site facilities were hub-and-spoke centers staffed by large group practices. Overall, the information suggests that the off-site PCI programs in this study have demonstrated a strong commitment to the classic Donabedian triad of structure, process, and outcomes measurements (30).

Study limitations. First, this study is subject to the usual concerns regarding observational registry data. There may be an inherent bias in off-site PCI programs that are either mandated by regulatory agencies or choose on their own to participate in the NCDR. Participants in any registry may be prone to "game" the system, particularly if score carding and public disclosure is an issue.

Second, this study includes outcomes up to the time of hospital discharge. Data regarding long-term outcomes are not currently captured in the NCDR CathPCI Registry. In addition, outcomes are assessed and analyzed on an institutional level, not on an individual operator level.

Third, specific in-depth details regarding clinical presentation, case selection, procedural complications, morbidity, and mortality were sometimes beyond the purview of the basic datasets. However, a special data clarification effort was utilized to resolve the 172 of 8,736 off-site patients (2%) for whom mortality or transfer data were questioned, resulting in clarification of 154 of these patients (90%), leaving 18 of 8,736 (0.2%) not clarified. A sensitivity analysis confirmed that the unclarified data would not have affected the risk-adjusted mortality analysis results.

Fourth, although this NCDR study indicates that nonprimary PCI can be done safely at off-site facilities, the efficacy of truly elective PCI at off-site facilities can perhaps be best addressed by a large randomized prospective trial such as the C-PORT (Cardiovascular Patient Outcome Research Team) Elective Angioplasty Study, which is under way. However, such studies are difficult to conduct, and results may not be forthcoming for some time. In the interim, a comprehensive large database such as the NCDR CathPCI Registry offers a realistic and

relative contemporary quality assurance standard to monitor these issues. Based on the experiences gained with this current study, the NCDR plans to sponsor a proactive comprehensive working group of off-site PCI centers to further communicate and track outcomes. This effort will coincide with the upcoming transition to the next CathPCI database version 4.0.

Finally, a participation bias cannot be excluded. The total number of PCI centers in the U.S. that do not have surgery on site is not definitively known (22) but may number ≈250. Of these, it is estimated that one-third submit data to another peer-reviewed registry, a spoke and hub partner database, or a multicenter trial. Thus, the 60 off-site PCI facilities in this NCDR study may represent a minority of such programs in the nation and are probably in the upper tier of quality. With this perspective, the results reported here may not be applicable to all PCI centers without surgical backup on site, particularly those that do not participate in any formal data registry or clinical trial.

Conclusions

Compared with on-site PCI centers, off-site PCI programs in the NCDR were predominantly located in nonurban areas, had lower annual PCI volume, treated a higher percentage of patients who presented with subsets of MI, and had better reperfusion times in primary PCI. Off-site PCI centers had similar observed procedure success, morbidity, emergency cardiac surgery rates, and mortality in cases that required emergency surgery. The risk-adjusted mortality rates in off-site PCI facilities were comparable to those of PCI centers that had cardiac surgery on site, regardless of whether PCI was performed as primary therapy for STEMI or in a nonprimary setting.

These findings should not be extrapolated to encourage the widespread proliferation of more PCI programs without surgery on site to fulfill a political or an economic agenda. Rather, our study does confirm the safety of an off-site strategy at PCI centers where rigorous clinical, operator, and institutional criteria are in place and where data are submitted and reviewed in a comprehensive multicenter registry such as the NCDR.

Acknowledgments

The authors would like to thank Jessica Morris, MBA, and Kristi Mitchell, MA, MPH, of the NCDR for their tireless work and outstanding efforts in the conduct of the data clarification project. Tammy Davis and Susan Queen of Wake Forest University School of Medicine deserve special thanks for their expertise in the preparation of this paper.

EXECUTIVE SUMMARY

- Cardiovascular diseases (CVD) are a great public health concern. CVD account for about one-third of all Connecticut resident deaths. Coronary heart disease (CHD), cerebrovascular disease (stroke) and heart failure (HF) are the main types, accounting for 48%, 15%, and 8% respectively of all CVD deaths.

- The CVD, CHD, and stroke age-adjusted mortality rates of Connecticut residents decreased significantly between 1999 and 2008.

- Approximately 55% of all Connecticut resident CVD deaths are among females. However, males have significantly higher age-adjusted CVD mortality rates (2006-2008 data).

- Black Connecticut residents have the highest age-adjusted CVD mortality rate as well as higher age-adjusted CVD, CHD, and stroke premature mortality rates compared with White and Hispanic residents (2006-2008 data).

- Hispanic Connecticut residents have significantly lower age-adjusted CVD and CHD mortality rates than White residents (2006-2008 data).

- About 18% of all hospital discharges in Connecticut are due to CVD. Approximately 26% of CVD hospitalizations are due to CHD, 12% to stroke, and 18% to HF (2008 data).

- Connecticut male residents have higher age-adjusted rates of hospitalizations for CVD, CHD, stroke, and HF than female residents. Black Connecticut residents have higher rates of hospitalizations for CVD, stroke, and HF than White and Hispanic residents (2008 data).

- About $2.2 billion was billed for CVD hospitalizations in Connecticut in 2008. Approximately 34% of CVD charges are for CHD, 12% for stroke, and 12% for HF. CVD also incur enormous indirect costs.

- Risk factors for CVD may be modifiable or non-modifiable. Key modifiable risk factors are high blood pressure, high blood cholesterol, smoking, diabetes, obesity, and physical inactivity. Non-modifiable risk factors include increasing age and family history of heart disease and stroke.

- High blood pressure (HBP) is a major risk factor for heart attack and stroke. About 27% of Connecticut adults have HBP. Connecticut males are more likely than females to have HBP. About 25% of White, 36% of Black, and 22% of Hispanic adults in Connecticut have HBP. Also, Connecticut adults with lower annual household incomes are more likely to have HBP compared to adults with higher annual household incomes (2007-2009 data).

- High blood cholesterol (HBC) is a major risk factor for CHD. About 38% of Connecticut adults have HBC. Connecticut males are more likely than females to have HBC. The prevalence of HBC increases with age. Black and Hispanic Connecticut adults are less likely than White adults to have had their blood cholesterol tested. Connecticut adults with lower annual household incomes are less likely than adults with higher annual household incomes to have had their blood cholesterol tested (2007-2009 data).

- Cigarette smoking increases the risk of heart attack, stroke, and death from CHD. About 16% of Connecticut adults are current smokers. Current adult smokers are more likely to be younger, have lower annual household incomes, and be less educated. Among adults, smoking rates do not vary significantly by gender or race and ethnicity (2007-2009 data). According the 2009 Connecticut School Health Survey, 15.3% of high school students are current smokers. White high school students are more likely than Black and Hispanic students to be current smokers.

- Diabetes has been recognized as a major risk factor for CVD. An estimated 6.9% of Connecticut adults have diagnosed diabetes. Connecticut males are more likely to have diabetes than females. Also, high rates of diabetes are associated with older age, lower socioeconomic position, and racial and ethnic minority status. About 5.6% of White, 14.9% of Black, and 10.5% of Hispanic adults in Connecticut have diabetes (2007-2009 data).

- Obesity is an independent risk factor for CVD. An estimated 10.4% of high school students in Connecticut are obese. High school males are more likely to be obese than females and Hispanic students are more likely to be obese than White and Black students (2009 data). Approximately 21% of Connecticut adults are obese. Older adults are more likely to be obese than younger adults; males are more likely to be obese than females; and those with lower annual household incomes are more likely to be obese than those with higher annual household incomes. Also, Black and Hispanic adults are more likely to be obese than White adults (2007-2009 data).

- Physical inactivity is associated with an increased risk of a number of chronic health conditions including CHD, high blood pressure, and obesity. Approximately 47% of Connecticut adults participate in less than the recommended amount of physical activity. Older adults, females, and adults with lower annual household incomes have higher rates of physical inactivity. About 44.5% of White, 59.7% of Black, and 54.2% of Hispanic Connecticut adults are physically inactive (2007-2009 data).

- The co-prevalence of risk factors places an individual at elevated risk for CHD and stroke. About 42% of Connecticut adults have two or more modifiable risk factors for CVD (2007-2009 data).

- Early recognition of the signs and symptoms of heart attack and stroke increase the likelihood of immediate emergency transport to the hospital and timely medical care. Only 13.6% of Connecticut adults can identify all the proper heart attack signs and only 22.6% can identify all the proper stroke signs. Women tend to be more knowledgeable than men about the signs and symptoms of heart attack and stroke (2007-2009 data).

- Access to health care is crucial to the prevention, treatment, and management of CVD. About 9% of adults in Connecticut do not have health insurance. Approximately 6% of White, 21% of Black, and 30% of Hispanic adults in Connecticut do not have health insurance (2007-2009).

- Targeted public health interventions are warranted for all Connecticut residents with multiple risk factors. Special emphasis should be placed on evidence-based interventions that address risk factor reduction among Black, Hispanic, and lower-income Connecticut adults.

THE BURDEN OF CARDIOVASCULAR DISEASES IN CONNECTICUT

INTRODUCTION

Cardiovascular disease refers to a wide variety of heart and blood vessel diseases. The most common forms of cardiovascular disease are coronary heart disease (CHD) and cerebrovascular disease. Essential hypertension, heart failure (HF), and atherosclerosis are other common cardiovascular diseases (CVD).[1] CVD are of great public health concern because more than one-third of all deaths in Connecticut are due to CVD and because prevention efforts have shown great potential in reducing the morbidity, mortality, and disability of CVD.[2, 3]

MORTALITY

CVD accounted for 9,351 Connecticut resident deaths in 2008, or about 33% of all deaths for the period. In contrast, cancer deaths accounted for 24%; chronic lower respiratory disease, 5%; unintentional injuries, 5%; and diabetes, 2% of all Connecticut resident deaths (Table 1).[3]

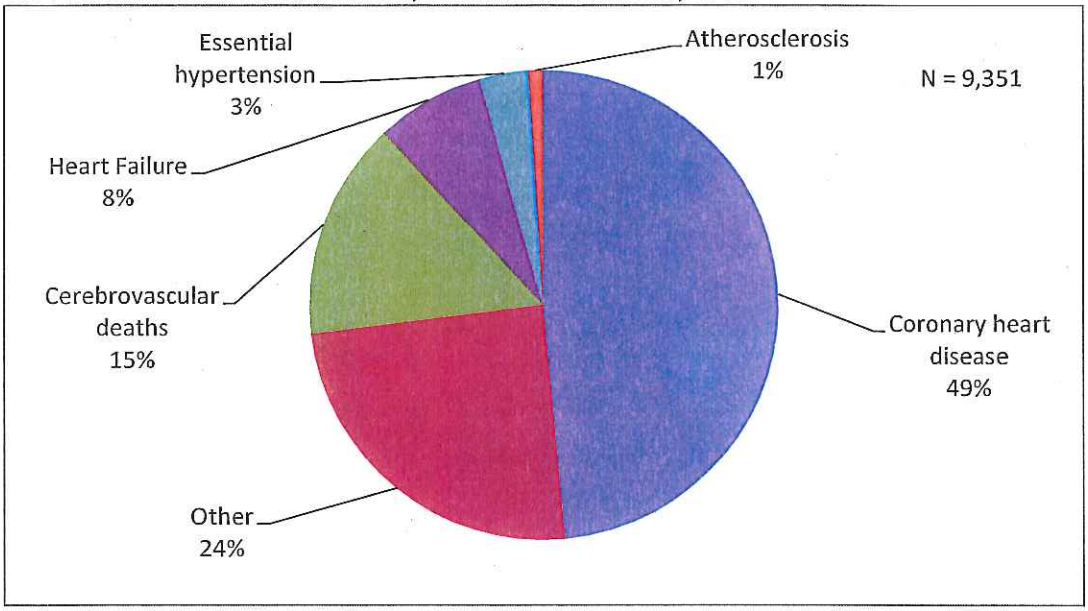
Table 1. Connecticut Resident Deaths, 2008

Cause of Death	Number of Deaths	Percent of Deaths
All Causes	28,749	100%
Cardiovascular Disease	9,351	33%
Cancer	6,765	24%
Chronic Lower Respiratory Disease	1,494	5%
Unintentional Injury	1,362	5%
Alzheimer's Disease	831	3%
Pneumonia and Influenza	688	2%
Diabetes	618	2%

Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

The major CVD are CHD and cerebrovascular disease or "stroke". Stroke is the most severe clinical manifestation of cerebrovascular disease, and the terms are used interchangeably in this report.[4] CHD accounts for 49% of all CVD deaths and includes hypertensive heart disease and ischemic heart disease (2008 data). Stroke is responsible for about 15% of CVD deaths in Connecticut, and includes two major types - ischemic stroke and hemorrhagic stroke. HF accounts for 8% of all CVD deaths, while essential hypertension and atherosclerosis account for 4% of all CVD deaths in Connecticut (Figure 1).[3]

Figure 1. Cardiovascular Disease Deaths, Connecticut Residents, 2008

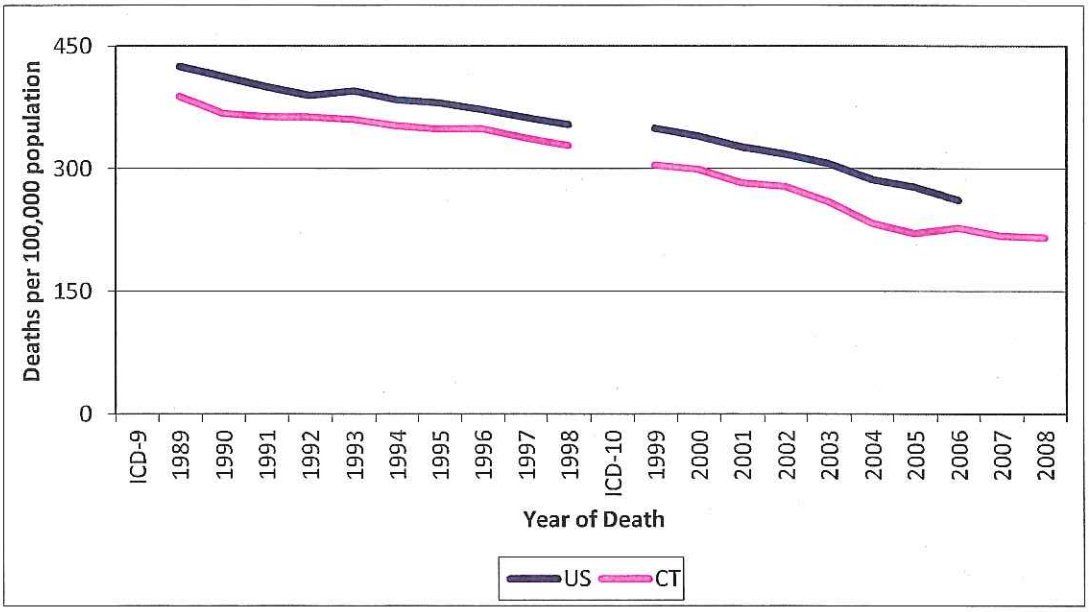


Sources: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Trends in Age-adjusted Mortality

Since the 1990s, CVD and CHD mortality rates* have decreased significantly for all Connecticut residents.[5, 6] This continuing decrease in Connecticut CVD and CHD mortality rates mirrors a similar decline in CVD and CHD mortality rates nationwide.[7] CVD and CHD mortality rates for Connecticut residents have been consistently lower than those for the United States population (Figure 2 and Figure 3).[3, 7] Since 2001, the Connecticut resident CHD mortality rate has been below the *Healthy People 2010* target of 166 per 100,000 population (Figure 3). There is no *Healthy People 2010* target for CVD.[8]

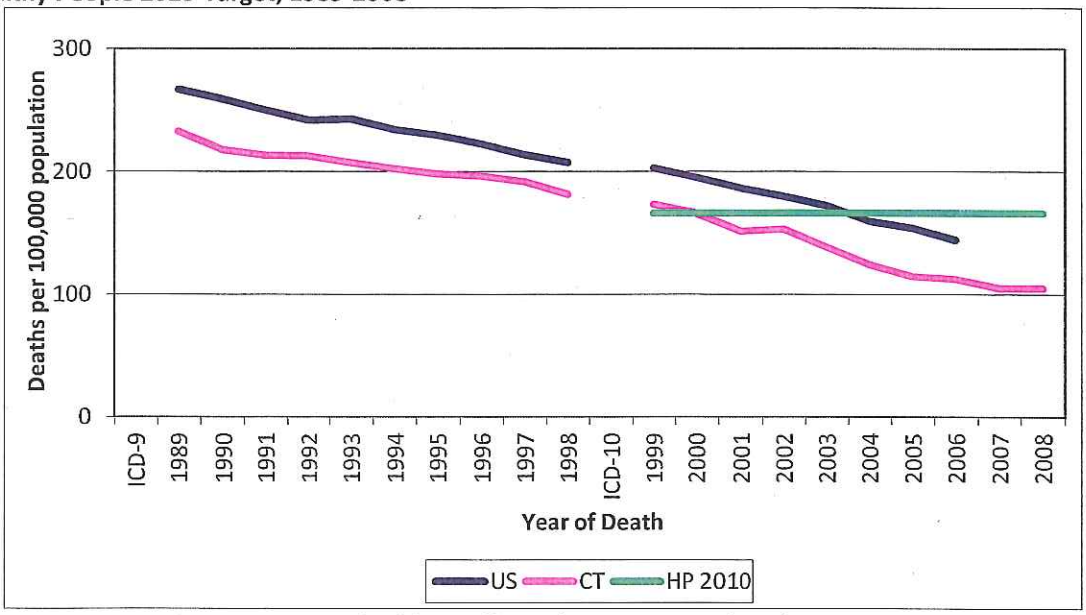
Figure 2. Age-adjusted Mortality Rates for Cardiovascular Disease, Connecticut & United States, 1989-2008



Sources: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 codes: 390-459.9 (1989 to 1998); ICD-10 codes: I00-I78.9 (1999 to 2008).

* The mortality rates presented in this report are age-adjusted mortality rates (AAMR). The AAMRs were computed by the direct method using the 2000 U.S. standard million population. The AAMRs were calculated using the death records of Connecticut residents.

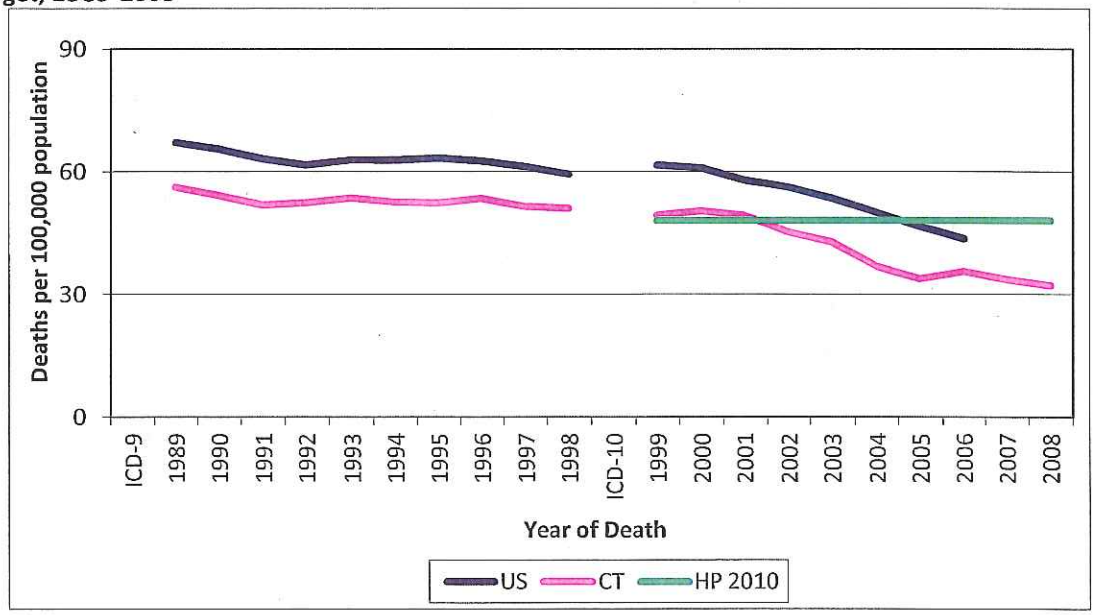
Figure 3. Age-adjusted Mortality rates for Coronary Heart Disease, Connecticut, United States, & Healthy People 2010 Target, 1989-2008



Source: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 codes: 402,410-414, 429.2 (1989 to 1998); ICD-10 codes: I11, I20-25 (1999 to 2008).

Stroke mortality rates of Connecticut residents did not change significantly in the 1990s.[5] However, decreasing trends have been observed since 1999.[6] Connecticut resident mortality rates from stroke have been consistently lower than those of the U.S.[7] Since 2002, the Connecticut resident stroke mortality rate has been below the *Healthy People 2010* target of 48 per 100,000 population (Figure 4).[3, 8]

Figure 4. Age-adjusted Mortality Rates for Stroke, Connecticut, United States, & Healthy People 2010 Target, 1989-2008

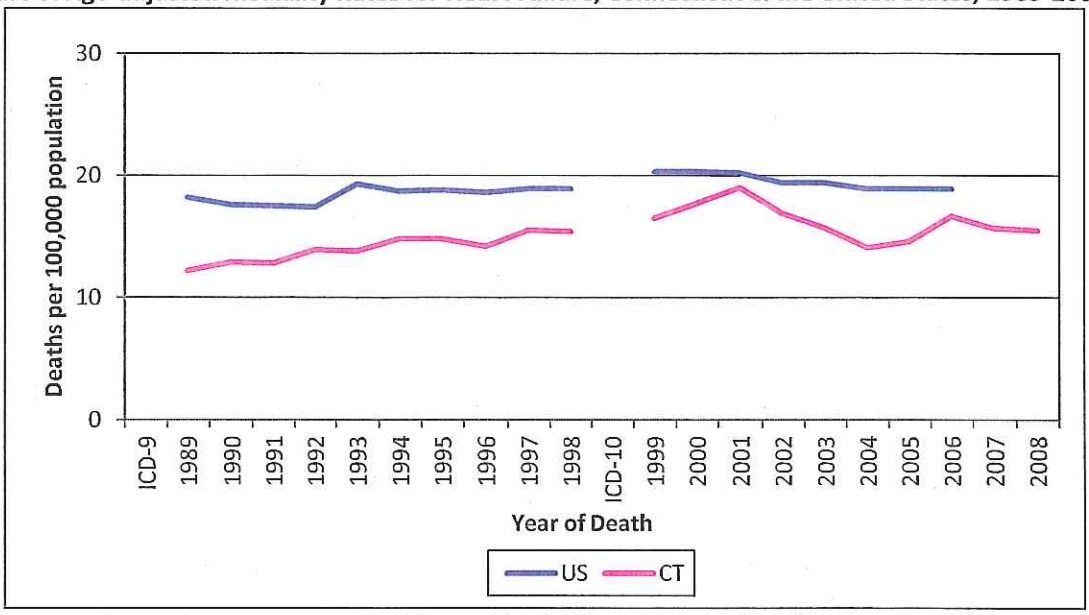


Sources: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 codes: 430-438 (1989 to 1998); ICD-10 codes: I60-69 (1999 to 2008).

During the 1990s, the Connecticut resident HF mortality rates increased significantly.[5] The increase in the HF mortality rates throughout the 1990s has been attributed to more people surviving heart attacks experienced earlier in life and to the aging population.[1] Approximately 60% of all HF deaths in Connecticut occur in persons aged 85 or older. In contrast, 45% of all CHD deaths and 49% of all cerebrovascular disease deaths occur in persons 85 and older.[7] The 2006-2008 Connecticut resident HF mortality rate was significantly lower than the 1999-2001 rate [data not shown]; however, linear trend analyses of HF mortality rates did not show a statistically significant change ($p \leq 0.05$) for the period 1999-2008.[3,6]

Connecticut HF mortality rates have been consistently lower than those of the U.S.[3,7] There is no *Healthy People 2010* target for HF (Figure 5).[8]

Figure 5. Age-adjusted Mortality Rates for Heart Failure, Connecticut & the United States, 1989-2008



Sources: Connecticut Department of Public Health, Vital Statistics Mortality Files, 2010. Centers for Disease Control and Prevention, 2010. Note: Rates are adjusted to the 2000 US standard population. Classification includes deaths with ICD-9 code: 428.0 (1989 to 1998); ICD-10 code: 150.0 (1999 to 2008).

Mortality by Gender

Approximately 55% of all Connecticut resident CVD deaths are among females (2006-2008 data). While more females than males die from CVD in Connecticut, males have higher CVD mortality rates (Table 2). Connecticut males have a 45% higher mortality rate due to CVD compared with females, a 71% higher mortality rate due to CHD, and a 30% higher mortality rate due to HF ($p<0.001$ for all comparisons). The stroke mortality rates of Connecticut males and females do not differ significantly.[3]

Table 2. Cardiovascular Diseases Deaths and Age-adjusted Mortality Rates (AAMR) per 100,000 Population, Connecticut Residents, 2006-2008

Cause of Death	All		Male		Female	
	Deaths	AAMR	Deaths	AAMR	Deaths	AAMR
All Cardiovascular Diseases	28,369	219.7	12,889	266.8	15,480	184.4
Coronary Heart Disease	13,840	107.4	6,874	141.3	6,966	82.7
Stroke	4,385	33.8	1,646	34.5	2,739	32.6
Heart failure	2,139	16.0	863	18.6	1,276	14.4

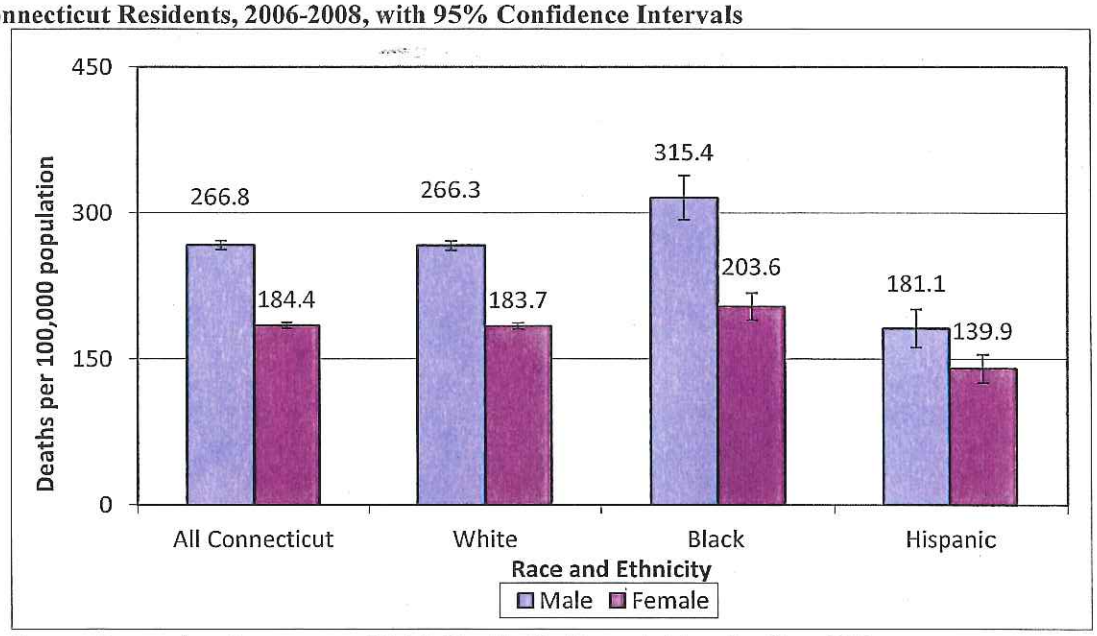
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Mortality by Gender, Race and Ethnicity

Cardiovascular Disease

The Connecticut resident CVD mortality rates differ by gender, race and ethnicity[†] with Black Connecticut residents having the highest CVD mortality rates (2006-2008 data). The CVD mortality rates of Black males and females are significantly higher than those of White males ($p<0.001$) and females ($p<0.05$), respectively. Black males and females also have significantly higher CVD mortality rates compared with Hispanic males and females ($p<0.001$ for both comparisons).[3] Conversely, Hispanic males and females have significantly lower mortality rates due to CVD than White males and females ($p<0.001$ for both comparisons) [Figure 6].[3] CVD mortality rates declined significantly for all subpopulation groups between 1999-2001 and 2006-2008 ($p<0.001$ for White and Black males and females; $p<0.005$ for Hispanic males; $p<0.01$ for Hispanic females) [data not shown].[3]

Figure 6. Age-adjusted Mortality Rates for Cardiovascular Disease by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



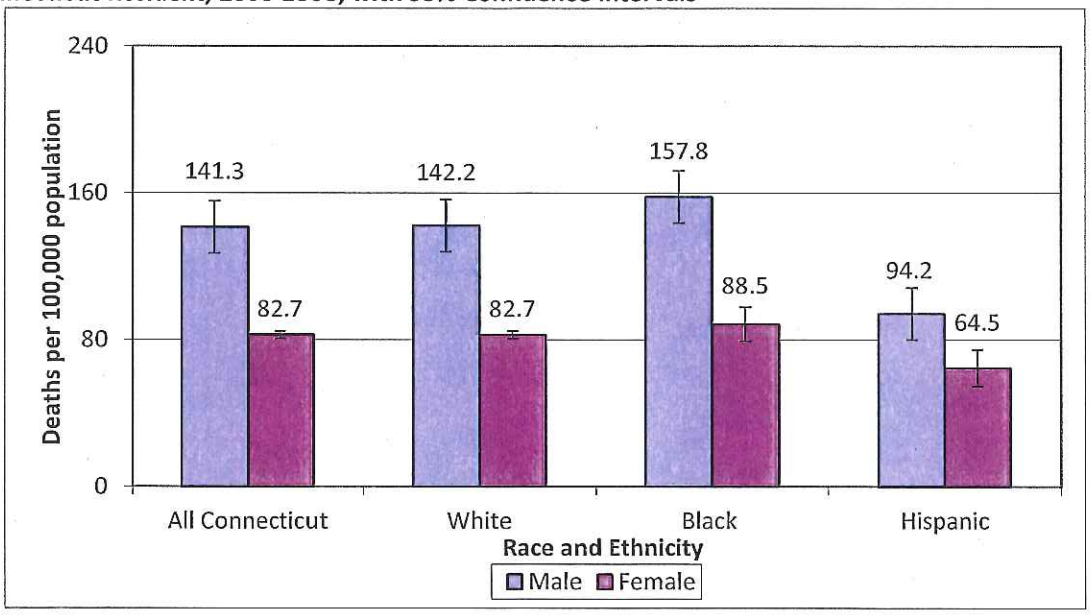
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

[†] Throughout this report racial groupings (e.g., "Black", "White") exclude persons of Hispanic ethnicity. A Hispanic ethnicity category is included in figures and tables reflecting data separate from race categories. Therefore, the modifier "non-Hispanic" is assumed.

Coronary Heart Disease

The CHD mortality rates differ somewhat by gender, race and ethnicity (2006-2008 data). Hispanic males and females have significantly lower CHD mortality rates than White males and females as well as Black males and females ($p < 0.001$ for males; $p<0.005$ for females) [Figure 7].[3] The CHD mortality rates of White males and females do not differ significantly from the rates of Black males and females (Figure 7).[3] CHD mortality rates declined significantly for all subpopulation groups in Connecticut between 1999-2001 and 2006-2008 ($p<0.01$ for Hispanic females; $p<0.001$ for other comparisons) [data not shown].[3]

Figure 7. Age-adjusted Mortality Rates for Coronary Heart Disease by Gender, Race and Ethnicity, Connecticut Resident, 2006-2008, with 95% Confidence Intervals

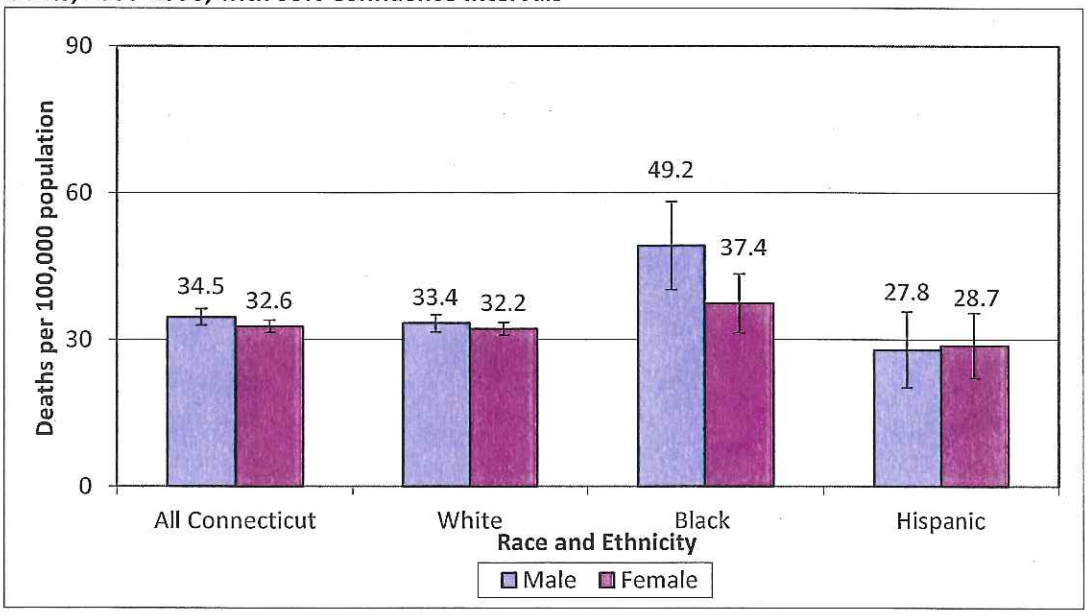


Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Stroke

Stroke mortality rates differ somewhat by gender, race and ethnicity (2006-2008). Black males have a significantly higher stroke mortality rate than White ($p<0.005$) and Hispanic males ($p<0.05$) [Figure 8].[3] However, the stroke mortality rates for Hispanic and White males do not differ significantly.[3] Likewise, the stroke mortality rates for White, Black, and Hispanic females do not differ significantly (Figure 8).[3] Stroke mortality rates declined significantly for White males ($p<0.001$), White females ($p<0.001$) and Black females ($p<0.005$) between 1999-2001 and 2006-2008 [data not shown].[3]

Figure 8. Age-adjusted Mortality Rates for Stroke by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals

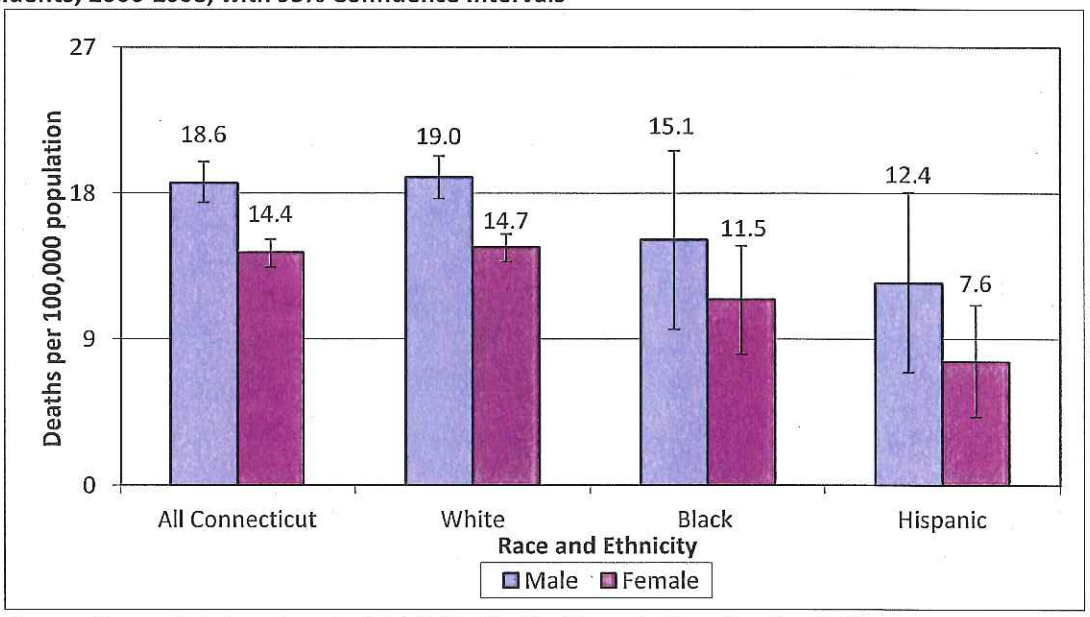


Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Heart failure

HF mortality rates vary little by gender, race and ethnicity (2006-2008 data). While the HF mortality rate of White females is significantly higher than the rate of Hispanic females ($p<0.005$), the HF mortality rate of White and Black females does not differ significantly [Figure 9].[3] The difference in the mortality rates of Black and Hispanic females does not reach statistical significance.[3] Also, the HF mortality rates of White, Black, and Hispanic males do not differ significantly [Figure 9].[3] White females and the overall Black Connecticut population experienced a statistically significant decline in the HF mortality rate between 1999-2001 and 2006-2008 ($p<0.05$ for both comparisons) [data not shown].[3]

Figure 9. Age-adjusted Mortality Rates for Heart Failure by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Premature Mortality by Gender, Race and Ethnicity

Premature mortality[‡], defined as the "years of potential life lost before age 75," focuses on deaths that occur at younger ages. For example, a person who dies at age 45 is considered to have lost 30 years of life, and a person who dies at 70 is considered to have lost 5 years of life.[9] Premature mortality is important because it emphasizes the years of productive life that are lost to society.

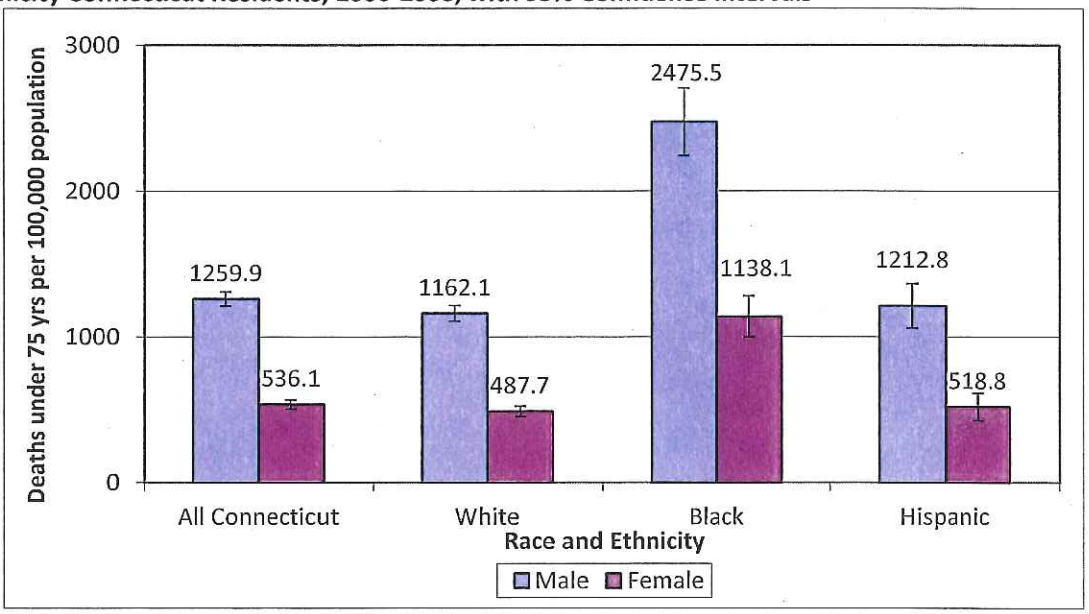
Cardiovascular Disease

CVD premature mortality rates differ by race and ethnicity as well as gender (2006-2008 data). Black males and females have significantly higher CVD premature mortality rates compared with White and Hispanic males and females ($p < 0.001$ for all comparisons) [Figure 10].[3] However, the CVD premature mortality rates of White males and females do not differ significantly from the rates of Hispanic males and females.[3] Also, males have significantly higher CVD premature mortality rates than females ($p<0.001$) (Figure 10).[3]

The CVD premature mortality rate declined significantly for the overall Connecticut population between 1999-2001 and 2006-2008 ($p<0.001$) [data not shown]. Similarly, CVD premature mortality rates declined significantly for White males ($p<0.001$), White females ($p<0.001$), Black females ($p<0.001$), Hispanic males ($p<0.05$), and Hispanic females ($p<0.05$) [data not shown]. CVD premature mortality rates for Black males did not change significantly from 1999-2001 to 2006-2008 [data not shown].[3]

[‡] The premature mortality rates presented in this report are age-adjusted "Years of Potential Life Lost (YPLL) under 75 years". Age-adjusted rates were computed by the direct method using the 2000 U.S. standard million population and Connecticut resident death records.

Figure 10. Age-adjusted Premature Mortality Rates for Cardiovascular Disease by Gender, Race and Ethnicity Connecticut Residents, 2006-2008, with 95% Confidence Intervals



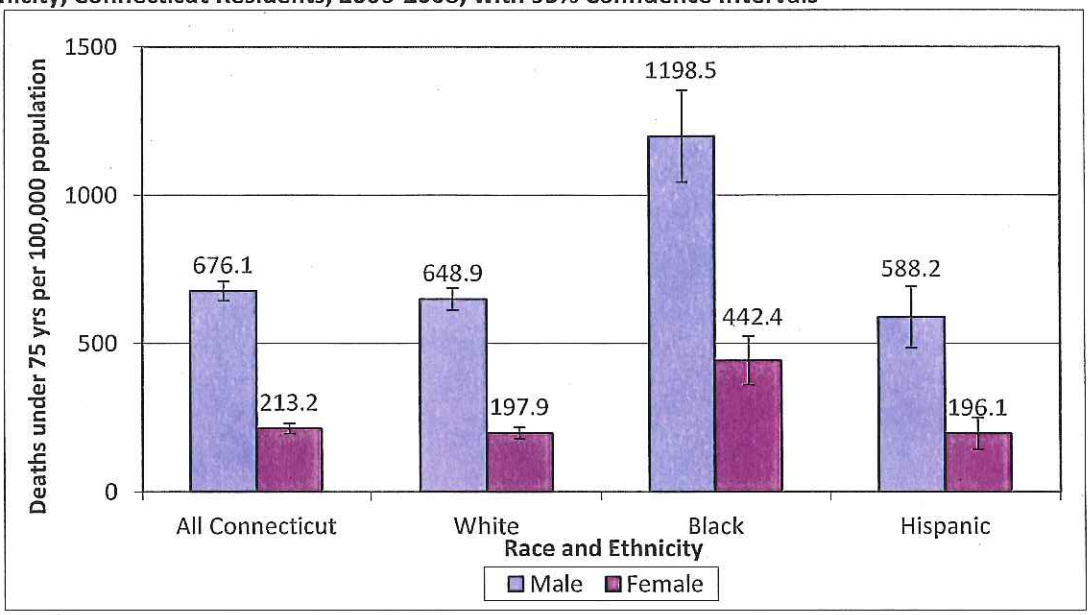
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Coronary Heart Disease

CHD premature mortality rates differ by race, ethnicity, and gender (2006-2008 data). The CHD premature mortality rates of Black males and females are significantly higher than those of White and Hispanic males and females ($p<0.001$ for all comparisons) [Figure 11].[3] However, the CHD premature mortality rates of White and Hispanic residents do not differ significantly.[3] Also, males have a significantly higher CHD premature mortality rate than females ($p<0.001$) [Figure 11].[3]

The CHD premature mortality rate declined significantly for the overall Connecticut population between 1999-2001 and 2006-2008 ($p<0.001$) [data not shown]. Similarly, CHD premature mortality rates declined significantly for all subpopulation groups (White males, $p<0.001$; White females $p<0.001$; Black males, $p<0.05$; Black females, $p<0.001$; Hispanic males, $p<0.005$; and Hispanic females, $p<0.05$) [data not shown].[3]

Figure 11. Age-adjusted Premature Mortality Rates for Coronary Heart Disease by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



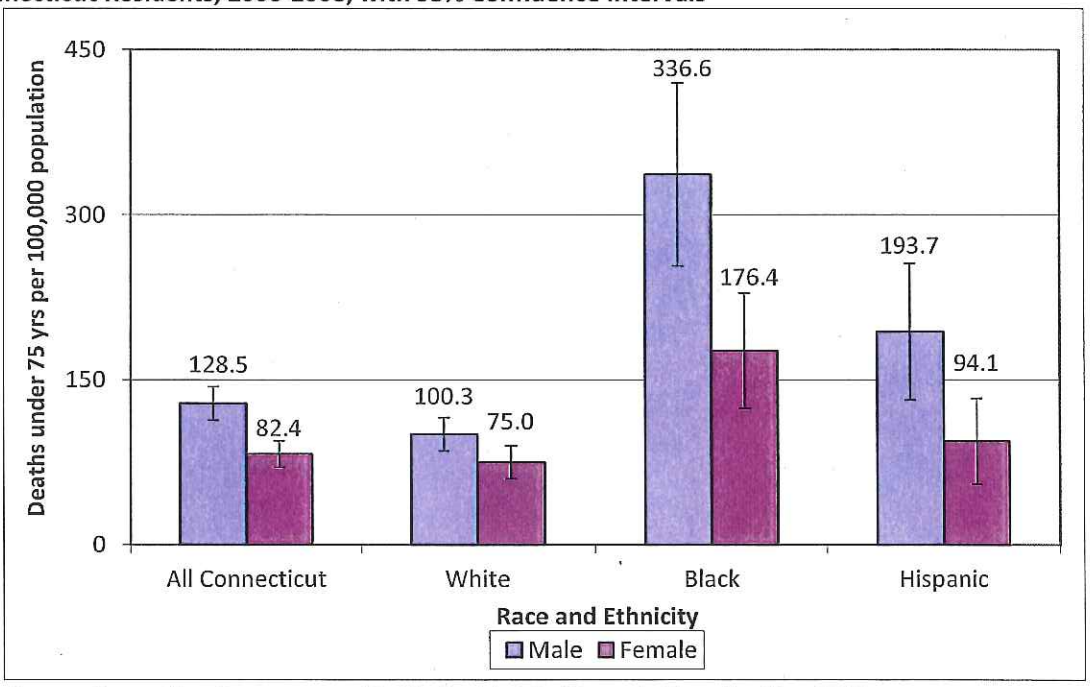
Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Stroke

Stroke premature mortality rates vary by gender, race and ethnicity (2006-2008 data). Overall, males have a significantly higher stroke premature mortality rate than females ($p<0.005$) [Figure 12].[3] The stroke premature mortality rates of Black and Hispanic males are significantly higher than that of White males ($p<0.001$ for Black and White male comparison; $p<0.05$ for Hispanic and White male comparison) [Figure 12].[3] However, the stroke premature mortality rates of Hispanic and Black males do not differ significantly.[3] While Black females have a significantly higher stroke premature mortality rate than White females ($p<0.005$), the stroke premature mortality rates of Hispanic and White females are not statistically different [Figure 12].[3] Also, the stroke premature mortality rates of Black and Hispanic females do not differ significantly.[3]

The stroke premature mortality rate declined significantly for the overall Connecticut population ($p<0.005$), White males ($p<0.05$), and White females ($p<0.05$) between 1999-2001 and 2006-2008 ($p<0.005$) [data not shown]. The decline in the stroke premature mortality rates for Black and Hispanic males and females do not reach statistical significance (data not shown).[3]

Figure 12. Age-adjusted Premature Mortality Rates for Stroke by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

Heart failure

The Connecticut resident HF premature mortality rate does not differ significantly by gender or race and ethnicity (Figure 13 and Figure 14) [2006-2008 data].[3] HF premature mortality rates did not decline significantly between 1999-2001 and 2006-2008 [data not shown].[3]

Figure 13. Age-adjusted Premature Mortality Rates for Heart Failure by Gender, Race and Ethnicity, Connecticut Residents, 2006-2008, with 95% Confidence Intervals

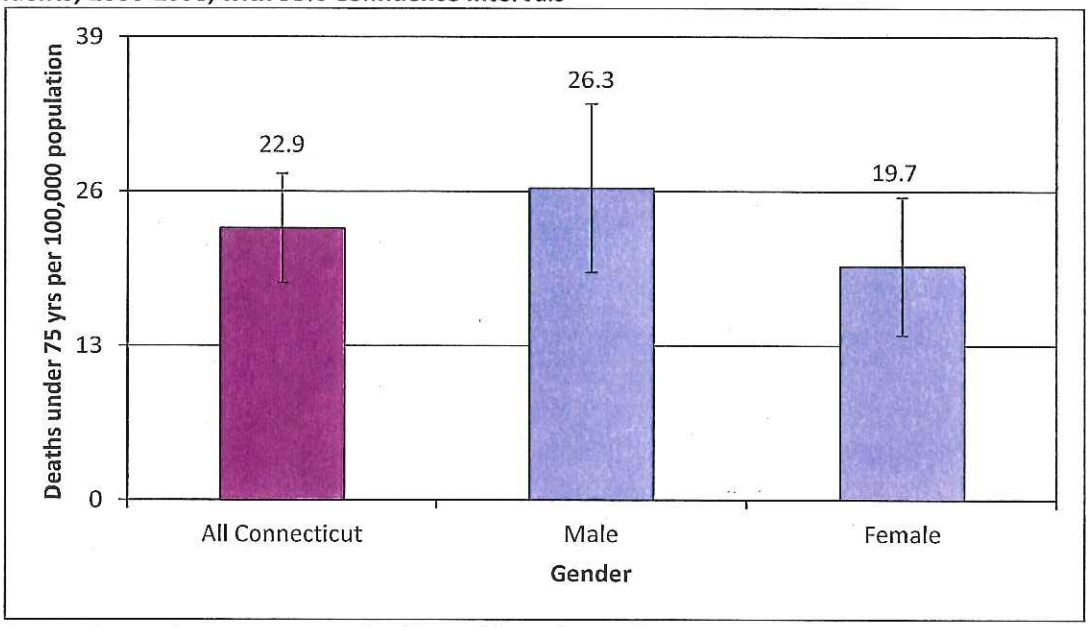
Figure 14. Age-adjusted Premature Mortality Rates for Heart Failure by Gender, Connecticut Residents, 2006-2008, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, Vital Records Mortality Files, 2010.

MORBIDITY

There were 59,664 Connecticut resident discharges from Connecticut hospitals for all CVD in 2008. This represents 18% of all hospital discharges (excluding pregnancy and childbirth related discharges) and 23% of all hospital billing charges in the state.[10] Approximately 26% of all CVD discharges are due to CHD, 12% are for stroke, and 18% are for HF. The median length of stay for CHD, stroke, and HF is two, three, and four days, respectively. The median length of stay for all hospital discharges in Connecticut is three days.[10]

Hospitalizations by Gender

Hospitalization rates[§] vary by gender (2008 data). Males have significantly higher rates of hospitalizations for all CVD, CHD, stroke, and HF compared with females ($p < 0.001$). More females than males, however, are hospitalized for stroke and HF [Table 3].[10]

Table 3. Hospitalizations and Age-adjusted Hospitalization Rates (AAHR) for Cardiovascular Diseases per 100,000 Population, Connecticut Residents by Gender, 2008

Diagnostic Group	All		Male		Female	
	Discharges	AAHR	Discharges	AAHR	Discharges	AAHR
All Cardiovascular Diseases	59,664	1,483.1	31,748	1,862.9	27,916	1,184.1
Coronary Heart Disease	15,779	392.0	9,877	559.2	5,902	254.2
Stroke	7,413	183.6	3,626	216.1	3,787	158.1
Heart failure	10,725	259.9	5,331	326.8	5,394	213.8

Source: Connecticut Department of Public Health, Connecticut Hospital Discharge Abstract and Billing Data Base, 2010.

[§]Hospitalization rates were calculated using 2008 Connecticut resident hospitalization discharge data and were age-adjusted based on the 2000 U.S. standard million population.

Hospitalization Rates by Race and Ethnicity

Hospitalization rates differ by race and ethnicity (2008 data). Black residents have significantly higher rates of hospitalizations for CVD, stroke, and HF than both White and Hispanic residents ($p<0.001$ for all comparisons). Black residents' rate of hospitalizations for CHD, however, is not significantly different than that of White and Hispanic residents.[10] Hispanic residents have significantly higher hospitalization rates for CVD ($p<0.001$) and CHD ($p<0.01$) than White residents. In contrast, Hispanic residents have a significantly lower rate of hospitalization for HF compared with White residents ($p<0.05$). Furthermore, the rates of hospitalization for stroke of Hispanic and White residents are not significantly different (Table 4).[10]

Table 4. Hospitalizations and Age-adjusted Hospitalization Rates (AAHR) for Cardiovascular Diseases per 100,000 Population, Connecticut Residents by Race and Ethnicity, 2008

Diagnostic Group	All		White, non-Hispanic		Black, non-Hispanic		Hispanic	
	Discharges	AAHR	Discharges	AAHR	Discharges	AAHR	Discharges	AAHR
All Cardiovascular Diseases	59,664	1,483.1	48,395	1,380.4	5,555	2,114.2	3,667	1,713.6

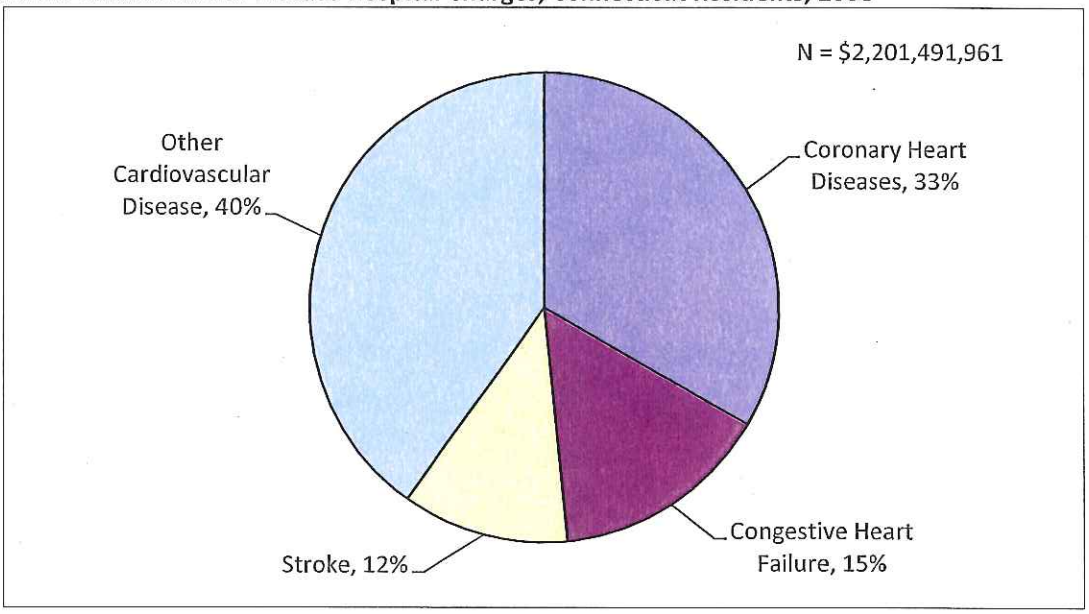
Source: Connecticut Department of Public Health, Connecticut Hospital Discharge Abstract and Billing Data Base, 2010.

Economic Costs

The estimated national annual cost for the medical management of CVD was $503.2 billion in 2010, or about $1600 per person.[2] This estimate includes direct medical costs and indirect costs. The indirect cost of CVD is associated with lost productivity from illness and premature death. Also, CVD are major causes of disability, limiting an individual's ability to live independently and negatively impacting the quality of life for individuals and families. For these reasons, CVD can incur enormous indirect costs. Assuming that disease rates and per person costs are the same in Connecticut as they are nationwide, the estimated economic burden of CVD in the state is about $5.8 billion. A large portion of these costs is attributable to inpatient hospitalizations.

Total Connecticut CVD hospital charges in 2008 were about $2.2 billion, with a median charge of $23,172 (Figure 15). About 33% of total CVD hospitalization charges were for CHD, 12% were for stroke, and 15% were for HF.[10] Median hospital charges were $34,792 for CHD, $19,772 for stroke, and $17,408 for HF. In contrast, the median charge for all hospital discharges in Connecticut was $16,727.[10]

Figure 15. Cardiovascular Disease Hospital Charges, Connecticut Residents, 2008



Source: Connecticut Department of Public Health, Connecticut Hospital Discharge Abstract and Billing Data Base, 2010.

RISK FACTORS

Risk factors for CVD may be non-modifiable (e.g., increasing age or family history) or modifiable (high blood pressure, high cholesterol, smoking, diabetes, obesity, physical inactivity) [Table 5]. Increasing age is a key risk factor for heart disease, stroke, and HF.[1] About 86% of all CVD deaths in Connecticut occur among those aged 65 years and older. About 85% of all CHD deaths, 90% of all stroke deaths, and 96% of all HF deaths in Connecticut occur among persons aged 65 years and older.[7] For men and women, major increases in the CVD mortality rate begin in the 35-to-44-year-old age group.[4] A family history of heart disease and stroke increases one's risk of developing these diseases. A combination of inherited characteristics and behavioral patterns (e.g. similar dietary, smoking, and activity habits) are thought to partially explain increased risk within families.[11]

Lower socioeconomic position (SEP) is an important risk marker for CVD. SEP is commonly measured by personal income, household income, or educational attainment level. Persons of lower SEP have higher CVD morbidity and mortality than do middle- or upper-income persons. Behavioral risk factors such as smoking, hypertension, and obesity are more prevalent in persons of lower SEP and may explain some of the observed disparity; however, other factors, like neighborhood socioeconomic environment, appear to have effects on individuals' risk for CVD.[1] Low-income neighborhood environments may contribute to increased CVD risk and poorer health outcomes because of such factors like poorer air quality, fewer food choices, and lower quality and/or lack of public services. Persons with lower incomes tend to have less access to and/or less effectively use preventive health services that are important to the early detection and treatment of hypertension.[12] While low-socioeconomic position may be considered "modifiable" in the sense that people can move in and out of poverty during a lifetime or over generations, it is not usually within a given individual's control to change his or her social position or neighborhood environment.

Table 5. Risk Factors for Cardiovascular Disease

Modifiable Risk Factors	Non-Modifiable Risk Factors
• High blood pressure • High cholesterol • Smoking • Diabetes • Obesity • Physical inactivity	• Increasing age • Family history

Modifiable Risk Factors

Current Connecticut Behavioral Risk Factor Surveillance System (BRFSS)** data show that about one out of three Connecticut adults report having one modifiable risk factor for CVD.[14] Following are summaries of the six main risk factors (high blood pressure, high blood cholesterol, tobacco use, diabetes, obesity, and physical inactivity) for CVD.

High Blood Pressure

High blood pressure (HBP) is a major risk factor for heart attack and the most important modifiable risk factor for stroke. People with elevated blood pressure (≥140 mmHg systolic / 90 mmHg diastolic) are 2 to 4 times more likely to develop CHD as are people with normal blood pressure (<120 mmHg systolic / 80 mmHg diastolic).[1] Studies have found that individuals with a normal blood pressure have approximately half the lifetime risk of stroke compared to those with high blood pressure.[13]

Approximately 27% of Connecticut adults report having HBP (2007-2009 data) compared with about 29% of adults nationwide (2009 data) (Figure 16).[14, 15] The risks for hypertension-related CVD increase markedly with age, as does the prevalence of hypertension, and drug treatment for HBP.[13] For example, 15.4% of Connecticut adults aged 35-44 years report having HBP compared with 57.8% of Connecticut adults aged 65 years and older ($p<0.001$) [data not shown].[14]

The rates of HBP also differ by gender. Approximately 27.4% of Connecticut males have HBP compared with 22.5% of females ($p<0.001$) [data not shown].[14]

The prevalence of HBP varies by race and ethnicity. Black Connecticut adults are more likely to have HBP than White and Hispanic Connecticut adults ($p<0.001$ for both comparisons). The rates of HBP among White and Hispanics adults do not differ significantly. About 25% of White, 36% of Black, and 22% of Hispanic adults report that they were told they had hypertension (Figure 17).[14]

** Unless otherwise stated, the BRFSS data presented in this report are based on 2007-2009 survey responses from non-institutionalized Connecticut adults.

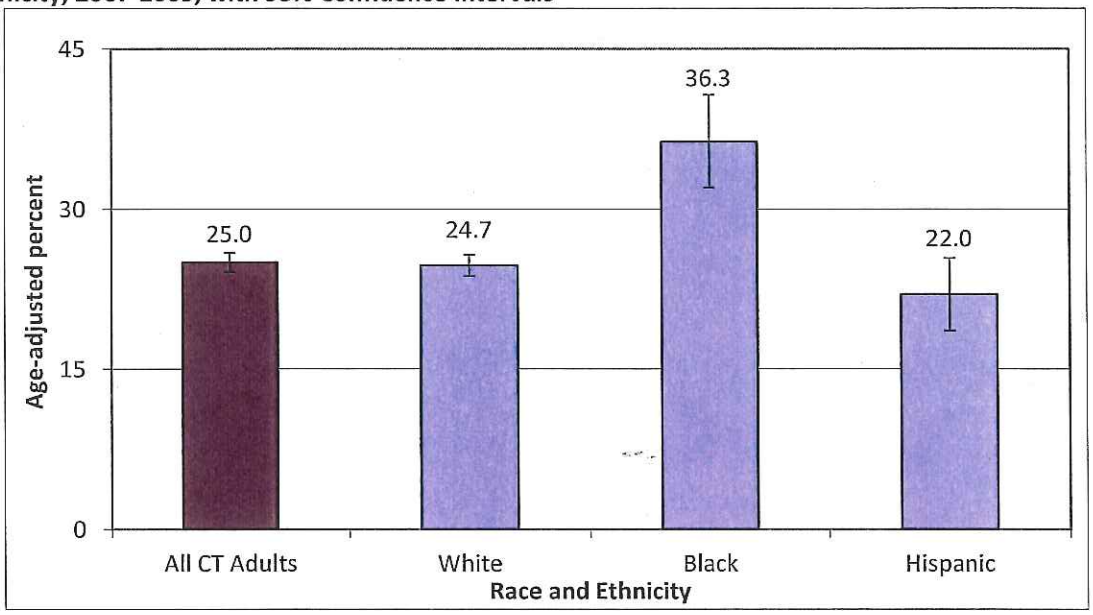
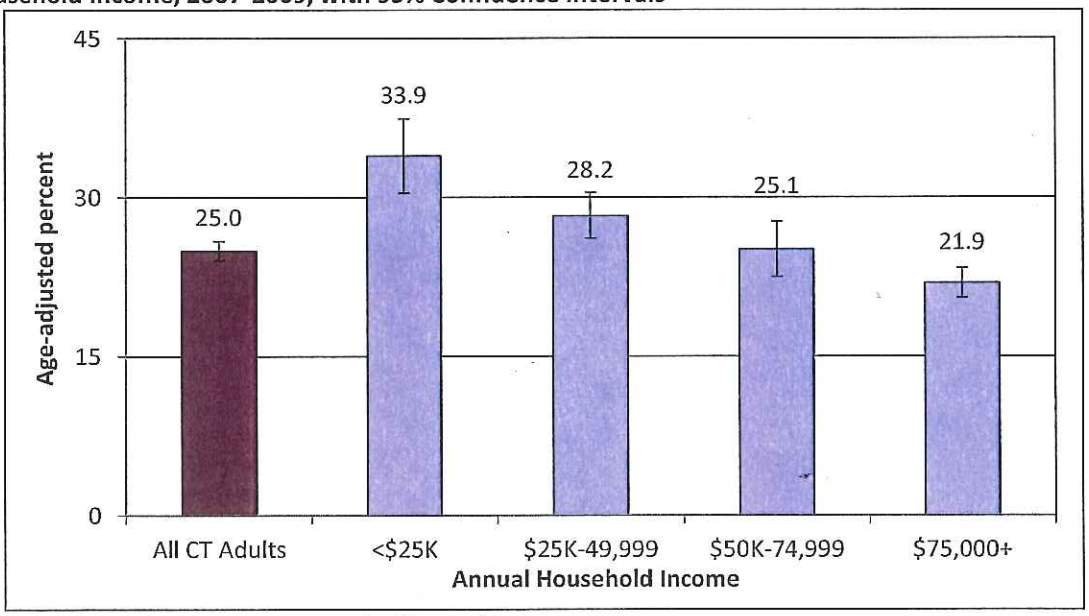
Figure 17. Age-adjusted Prevalence of High Blood Pressure among Connecticut Adults by Race and Ethnicity, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Connecticut adults with lower annual household incomes tend to have a higher prevalence of HBP compared to Connecticut adults with higher annual household incomes. For example, 33.9% of adults with an annual household income less than $25,000 have diagnosed HBP compared to 21.9% of adults with annual household income of at least $75,000 (p<0.001) [Figure 18].[14]

Figure 18. Age-adjusted Prevalence of High Blood Pressure among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

High Blood Cholesterol

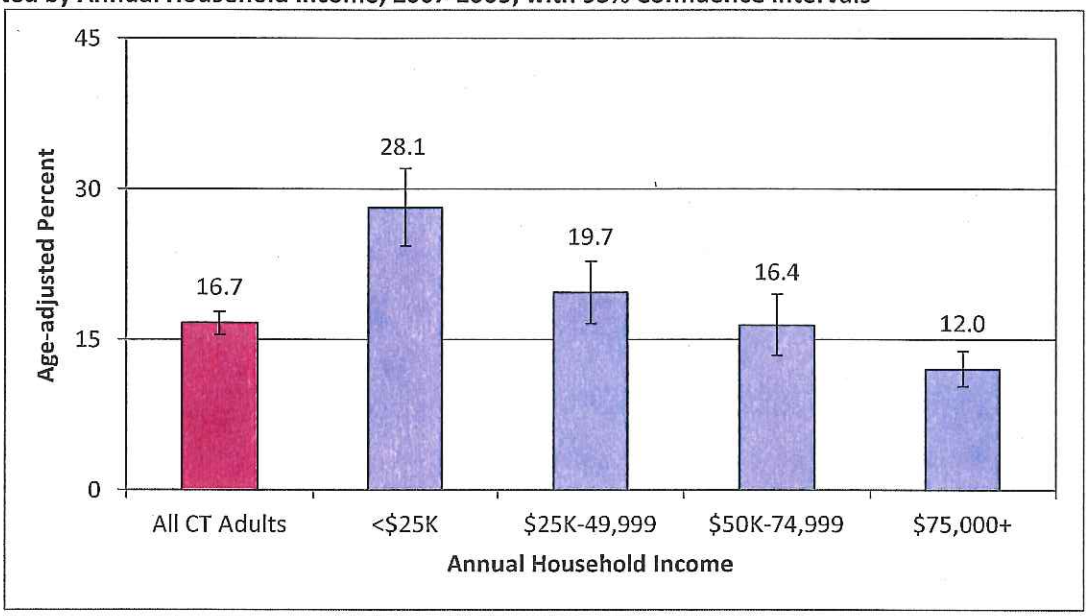
High blood cholesterol (HBC) is considered a major risk factor for CHD.[16, 17] Dyslipidemias, or an abnormal amount of lipids (e.g. high blood cholesterol) in the blood, were not traditionally regarded as a risk factor for stroke; however, a recent meta-analysis of statin therapy found that treatment of dyslipidemia decreases the risk of nonhemorrhagic stroke.[1] Control and reduction of HBC is important. A 10% decrease in total blood cholesterol levels may reduce the incidence of CHD by as much as 30%.[18]

About 38% of adults in Connecticut (2007-2009 data) and nationwide (2009 data) were told they had HBC (Figure 16).[14, 15] The prevalence of HBC increases with age. For example, 38.1% of Connecticut's adults aged 45-54 years report having HBC compared with 53.4% of Connecticut's adults aged 65 years and older ($p<0.001$) [data not shown].[14]

The prevalence of HBC also varies by gender. Approximately, 39.2% of Connecticut males have HBC compared with 29.7% of females ($p<0.001$) [data not shown]. [14]

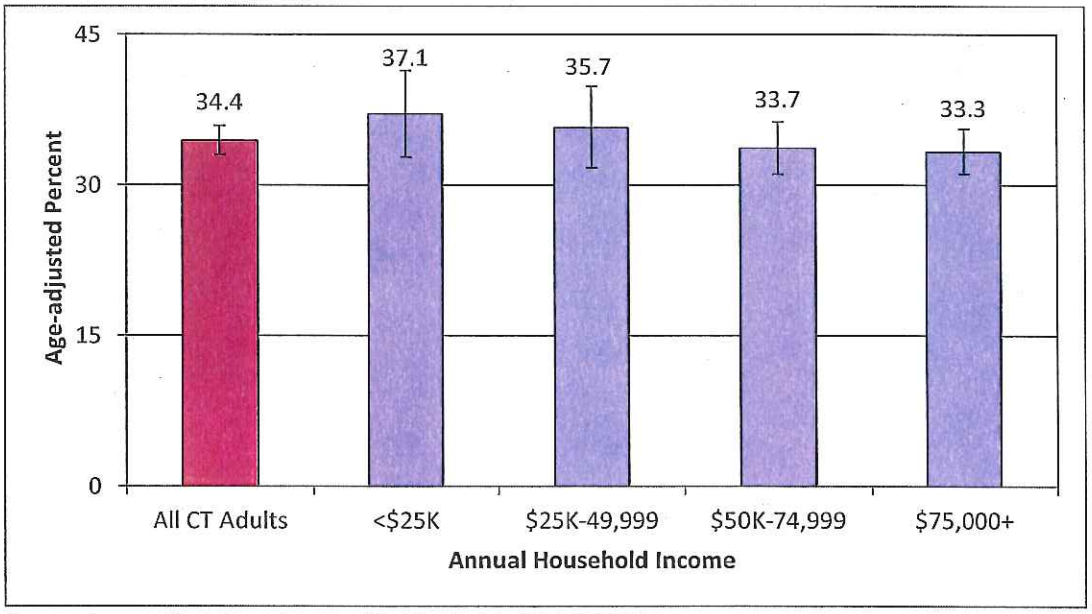
Connecticut adults compare favorably to adults nationwide in terms of cholesterol screening. About 82% of Connecticut adults report having had their blood cholesterol screened within the last five years (2007-2009 data) compared with 77% of adults in the U.S. (2009 data).[14, 15] Connecticut adults with lower incomes are more likely to report that they have never had their blood cholesterol tested compared to adults with higher incomes. For example, adults with annual household incomes less than $25,000 are significantly more likely to report that they have never had their blood cholesterol tested compared to individuals with annual household incomes of $75,000 or more ($p<0.001$) [Figure 19]. In contrast, the prevalence of HBC does not differ significantly by annual household income [Figure 20].[14]

Figure 19. Age-adjusted Percentage of Connecticut Adults Who Have Never Had Their Cholesterol Tested by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Figure 20. Age-adjusted Percentage of Connecticut Adults Who had Their Cholesterol Tested in the Past 5 Years and Were Told It was High by Annual Household Income, 2007-2009, with 95% Confidence Intervals

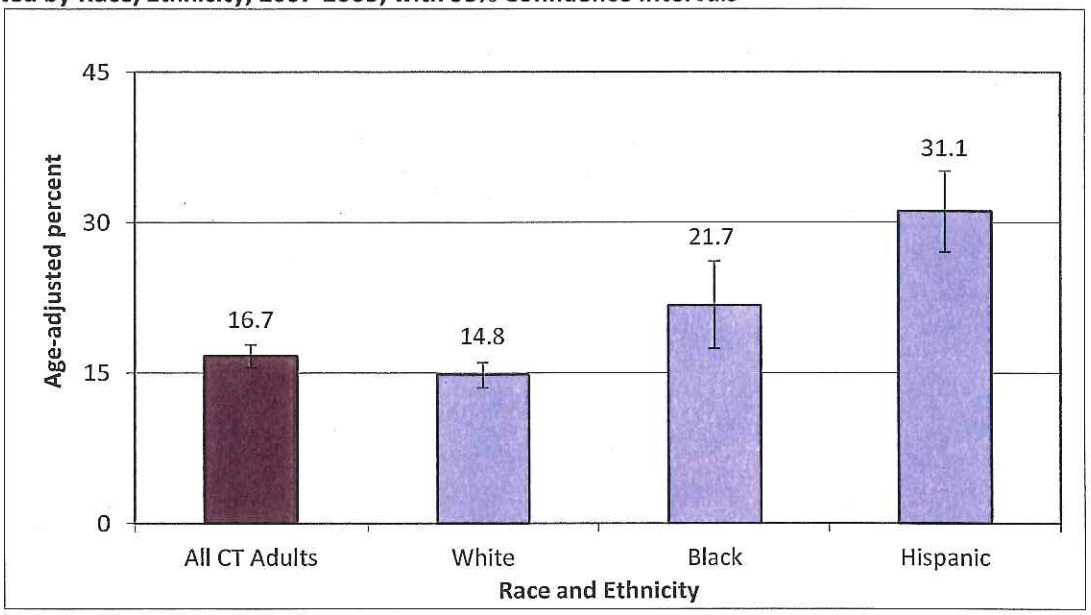


Source: Connecticut Department of Public Health, BRFSS, 2010.

Black and Hispanic adults are significantly more likely than White adults to report never having had their blood cholesterol tested ($p<0.05$ for Black and White comparison; $p<0.001$ for Hispanic and White comparison). Hispanic adults are also more likely than Black adults to report never having had their blood cholesterol tested ($p<0.05$). An estimated 14.8% of White, 21.7% of Black, and 31.1% of Hispanic adults report never having had their blood cholesterol tested [Figure 21]. In contrast, the prevalence of HBC does not differ significantly by race and ethnicity [data not shown].[14]

The rates of never having had blood cholesterol tested do not differ significantly by gender. Approximately, 16.9% of males and 16.4% of females in Connecticut have never had their blood cholesterol tested [data not shown].[14]

Figure 21. Age-adjusted Percentage of Connecticut Adults Who Have Never Had Their Cholesterol Tested by Race/Ethnicity, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Smoking

Cigarette smoking is a major modifiable risk factor for CVD. Smoking causes reduced blood vessel elasticity by increasing arterial wall stiffness. Smoking increases the risk of heart attack two-fold. Smokers have higher CHD mortality rates than non-smokers and the risk of death increases with greater number of cigarettes smoked. Current smokers have more than twice the risk of stroke compared with those who have never smoked. People who stop smoking decrease their stroke risk and their risk of CHD mortality.[1]

About 16% of Connecticut adults report being current smokers (2007-2009 data) compared with about 18% of adults nationwide (2009 data) [Figure 16].[14,15] According to the 2009 Connecticut School Health Survey (CSHS), 17.8% of high school students report being current smokers.[19]

Among adults, current smokers are more likely to be younger. For example, an estimated 22% of Connecticut adults aged 18 to 24 years old are current smokers compared with 14% of those aged 55 to 64 ($p<0.01$), and 6% of those aged 65 and older ($p<0.001$) [data not shown].[14] Smokers are also more likely to be individuals who have lower incomes and are less educated. For instance, about 31% of Connecticut's adults with annual household incomes under $25,000 are current smokers, compared to 10% of adults with annual household incomes of $75,000 or more ($p<0.001$) [Figure 22].[14] Similarly, about 31% of adults with less than a high school education report being current smokers compared to about 9% of adults who graduated from college ($p<0.001$) [data not shown].[14]

The rates of smoking do not differ significantly by gender. An estimated 16.8% of adult males and 15.2% of adult females are current smokers while an estimated 19.0% of high school males and 16.5% of high school females are current smokers (data not shown).[14,19]

Among Connecticut adults, smoking rates do not differ significantly by race and ethnicity. An estimated 15.8% of White, 19.1% of Black, and 15.6% Hispanic adults report being current smokers [data not shown].[14] However, the rates of smoking among high school students do vary by race and ethnicity. White Connecticut high school students are more likely to be current smokers than Black ($p<0.001$) and Hispanic ($p<0.05$) students. Also, Hispanic students are more likely than Black students to be current smokers ($p<0.05$) [Figure 23].[19]

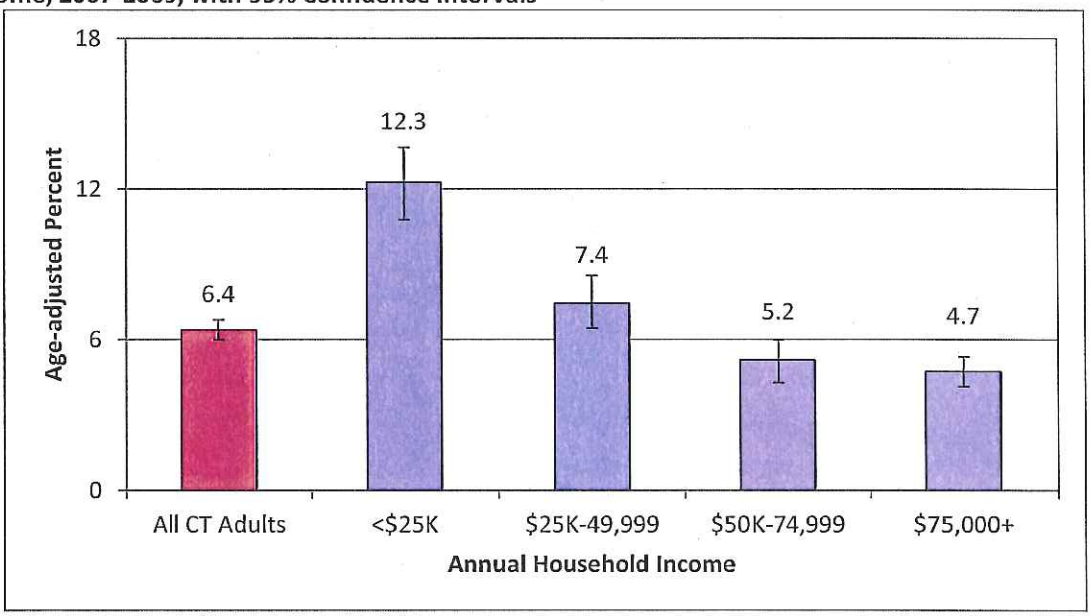
Source: Connecticut Department of Public Health, Youth Risk Behavior Surveillance System (YRBSS), 2010.

Diabetes

Diabetes has been recognized as a major risk factor for CVD. CVD is the primary cause of death for persons with diabetes, accounting for about 65% of the mortality. Individuals with diabetes are 2 to 4 times more likely to develop CHD and 2 to 5 times more likely to have a stroke than the rest of the population. People with diabetes often have HBP, HBC, and are overweight, further increasing their risk for CVD.[1]

An estimated 6.9% of Connecticut adults have diagnosed diabetes (2007-2009 data) compared with about 8% of adults nationwide (2009 data) [Figure 16].[14, 15] The prevalence of diabetes varies by gender, age, race and ethnicity, and SEP.[14, 20] Males are more likely to have diabetes than females. An estimated 7.3% of Connecticut males have diabetes compared with 5.7% of females ($p<0.005$) [data not shown].[14] Also, the prevalence of diabetes increases with age. Approximately 3% of adults aged 35-44 years report having diabetes compared to approximately 16.5% of adults aged 65 years and older ($p<0.001$) [data not shown].[14] Black and Hispanic adults have a significantly higher prevalence of diabetes compared with White adults ($p<0.001$ for both comparisons). The prevalence of diabetes among Black and Hispanic adults does not differ significantly. An estimated 5.6% of White, 14.9% of Black, and 10.5% of Hispanic adults report having diabetes [data not shown].[14] Adults with lower annual household incomes have a higher prevalence of diabetes compared to adults with higher annual household incomes. For example, approximately 12% of adults with annual household incomes under $25,000 report having diabetes, compared with about 5% of adults with household incomes over $75,000 ($p<0.001$) [Figure 24].[14]

Figure 24. Age-adjusted Prevalence of Diabetes among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Diabetes self-management education is essential because improperly controlled diabetes can result in CVD, kidney disease, blindness and loss of limb. It is, therefore, a particular concern that about 52% of Connecticut adults with diabetes report that they have never taken a course to manage the disease.[14]

Obesity

Body mass index (BMI), or weight adjusted for height, is a widely used screening method for obesity. For children and adolescents, BMI is compared to age- and gender-specific percentiles on the Centers for Disease Control and Prevention (CDC) growth charts. Children and adolescents with a BMI greater than or equal to the 85 percentile but less than the 95 percentile are considered overweight. Children and adolescents with a BMI greater than or equal to the 95 percentile are considered obese.[21] Medical guidelines for adults identify normal/desirable weight as a BMI under 25, overweight as a BMI of 25 to 29.9, and obese as a BMI of 30 or more. The prevalence of obesity has more than doubled over the past three decades in the United States.[21] The development of obesity involves social, behavioral, cultural, physiological, metabolic, and genetic factors. High calorie diets, along with less physical activity, have contributed to the obesity epidemic in our society.[21, 22]

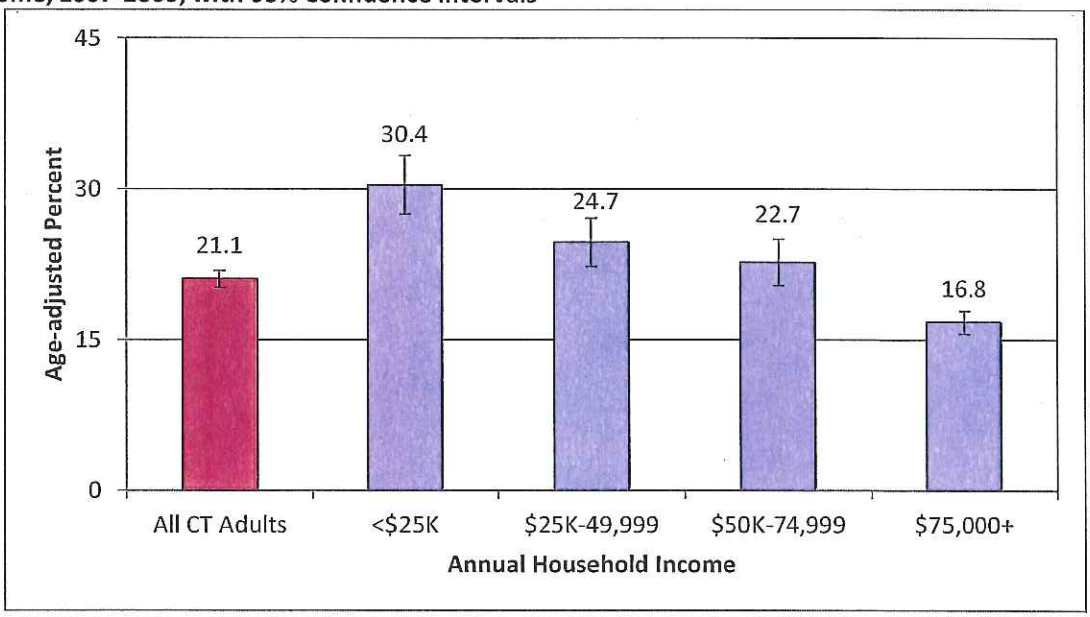
Obesity increases the risk of morbidity from hypertension, dyslipidemia, CHD, and stroke. All-cause mortality increases with increasing body weight.[22] Obesity is also an independent risk factor for CVD. The risk of ischemic stroke increases with increasing BMI. Studies have also suggested that body fat distribution may affect CHD risk. Upper body or abdominal fat seems to increase CHD risk regardless of BMI. Weight reduction can affect several of the modifiable risk factors for stroke thereby reducing the incidence of stroke.[1]

According to responses to the 2009 CSHS, an estimated 14.5% of Connecticut high school students were overweight and 10.4% were obese.[19] Obesity rates among high school students in Connecticut vary by gender and race and ethnicity. Male Connecticut high school students are significantly more likely to be obese than female high school students ($p<0.05$). An estimated 13.8% of male and 6.7% of female high school students in Connecticut are obese [data not shown].[19] Also, Hispanic Connecticut high school students have higher rates of obesity than both White ($p<0.001$) and Black ($p<0.05$) high school students. The difference in the rate of obesity among White and Black high school students does not reach statistical significance. An estimated 8.7% of White, 12.5% of Black, and 17% of Hispanic Connecticut high school students are obese [data not shown].[19]

An estimated 21% of Connecticut adults are obese (2007-2009 data) compared with about 27% of adults nationwide (2009 data) [Figure 16].[14, 15] Approximately 38% of Connecticut adults are overweight and 41% are neither overweight nor obese [data not shown].[14] Rates of obesity differ by SEP. For example, approximately 30% of adults with annual household incomes less than $25,000 are obese compared with 17% of those with annual household incomes over $75,000 ($p<0.001$) [Figure 25].[14] Rates of obesity also differ by race and ethnicity. Black and Hispanic adults are more likely to be obese than White adults ($p<0.001$ for both comparisons) [data not shown]. Black adults are also more likely to be obese than Hispanic adults ($p<0.05$). About 20% of White, 36% of Black, and 27% of Hispanic adults are obese [data not shown].[14] Furthermore, males are more likely to be obese than females. An estimated 27.9% of males are obese compared with 19.2% of females ($p<0.005$) [data not shown].[14] Additionally, older adults are more likely to be obese than younger adults. Approximately 11% of adults age 18-24 years are obese compared with 25% of adults aged 55-64 years ($p<0.001$) [data not shown].[14]

Obese adults are significantly more likely to report that they are in poorer health compared with non-obese adults. About 19% of adults who are obese report that they are in fair or poor health compared with about 9% of Connecticut adults who are not obese ($p<0.001$) [data not shown].[14]

Figure 25. Age-adjusted Prevalence of Obesity among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

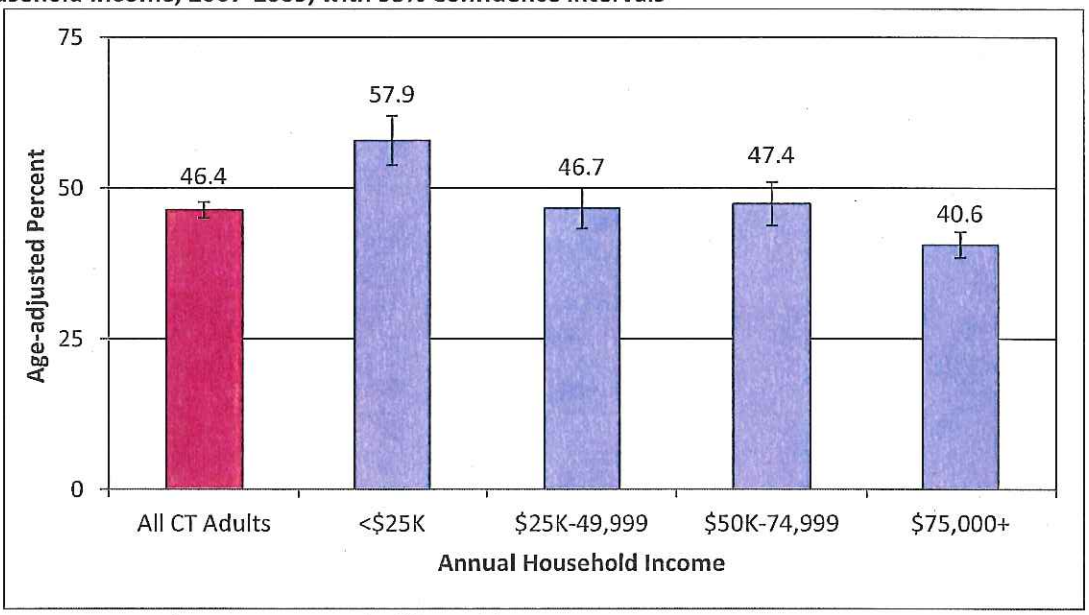
Physical Inactivity

Physical inactivity is associated with an increased risk of a number of chronic health conditions including CHD, diabetes, some cancers, HBP, obesity, and osteoporosis. Studies have shown that physical activity has protective effects on strokes.[1, 23]

The American College of Sports Medicine (ACSM), the American Heart Association (AHA), and the CDC recommend that healthy adults aged 18-65 years participate in moderate-intensity aerobic physical activity for a minimum of 30 minutes on five days per week or vigorous-intensity aerobic physical activity for a minimum of 20 minutes on three days per week.[24, 25] The guidelines are the same for adults aged 65 years and older; however, if older adults are unable to meet these guidelines because of chronic conditions, it is recommended that they participate in as much physical activity as possible.[25]

"Physical inactivity" is defined here as not meeting the recommendations of the ACSM, AHA, and CDC as described above. Approximately 47% of Connecticut adults report participating in less than the recommended amount of physical activity (2007-2009 data) compared with 49% nationwide (2009 data) (Figure 16).[14, 15] Rates of physical inactivity are higher among older adults, women, racial or ethnic minorities, and people with low incomes.[23] Physical inactivity increases with age. About 56% of adults 65 years old and older are physically inactive compared with about 48% of adults aged 45 to 64 years , and 43% of adults aged 18 to 44 years ($p<0.001$ for both comparisons) [data not shown]. Similarly, the physical inactivity rate among adults aged 45 to 64 years is significantly higher than that of adults aged 18 to 44 years ($p<0.005$) [data not shown].[14] Likewise, females are more likely to be physically inactive than males. An estimated 48.5% of adult females are physically inactive compared with 44% of adult males ($p<0.05$) [data not shown].[14] Additionally, Black and Hispanic adults are significantly more likely to report higher rates of physical inactivity than White adults ($p<0.001$ for Black and White comparison; $p<0.005$ for Hispanic and White comparison). The rates of physical inactivity among Black and Hispanic adults do not differ significantly. Approximately 44.5% of White, 59.7% of Black, and 54.2% of Hispanic adults report that they are physically inactive (data not shown).[14] Furthermore, adults with lower incomes are more likely to be physically inactive compared to adults with higher incomes. For example, about 58% of adults with annual household incomes of less than $25,000 are physically inactive compared to 41% of adults with annual household incomes of $75,000 or more ($p<0.001$) [Figure 26].[14]

Figure 26. Age-adjusted Prevalence of Physical Inactivity among Connecticut Adults by Annual Household Income, 2007-2009, with 95% Confidence Intervals



Source: Connecticut Department of Public Health, BRFSS, 2010.

Co-Prevalence of Cardiovascular Risk Factors

The co-prevalence of risk factors places an individual at elevated risk of CHD and stroke.[26] Approximately 42% of Connecticut adults report having two or more and 19% report having three or more modifiable risk factors for CVD.[14] The co-prevalence of risk factors contributes to the complexity of disease management.

RECOGNIZING THE SIGNS AND SYMPTOMS OF HEART ATTACK AND STROKE

The *Healthy People 2010* national objectives for both heart disease and stroke include increasing the proportion of persons who are aware of the early warning signs and symptoms of heart attack and stroke and the necessity of calling 911 when persons are suffering from either of these conditions (Table 6).[8] Early recognition of heart attack and stroke and calling 911 increase the likelihood of immediate emergency transport to the hospital and timely medical care that can reduce disability and death.

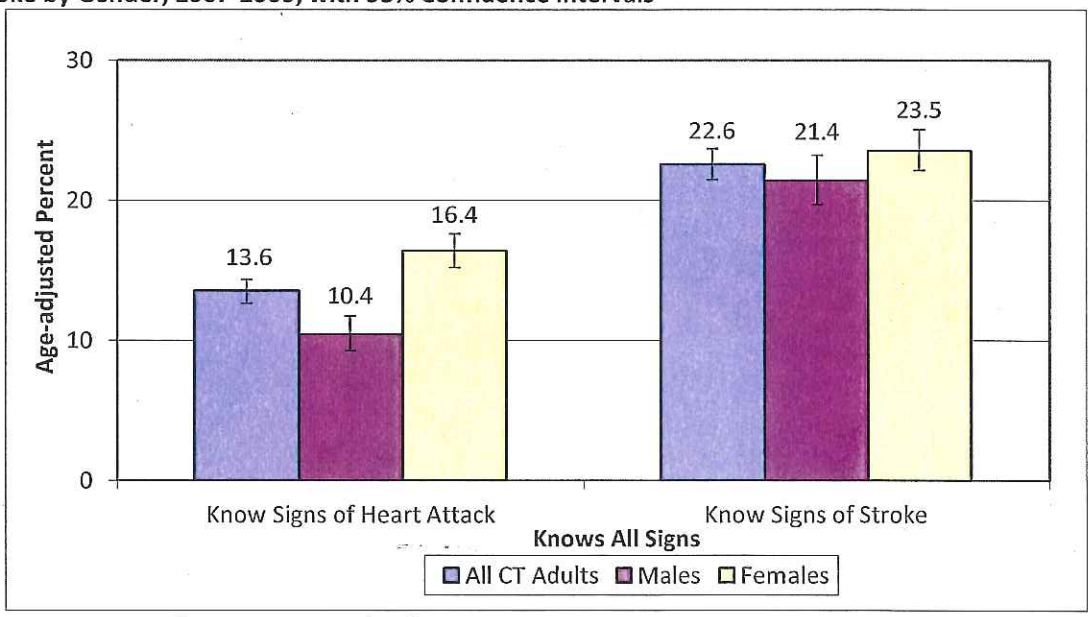
Table 6. Warning Signs for Heart Attack and Stroke

Heart Attack	Stroke
• Jaw, neck, back pain • Lightheaded, faint • Shortness of breath • Arm or shoulder discomfort • Chest pain or discomfort	• Severe headache with no known cause • Trouble seeing in one or both eyes • Confusion, trouble speaking • Trouble walking, dizziness, or loss of balance • Sudden numbness/weakness of face, arm, or leg

Source: American Heart Association, 2010.

The percentage of Connecticut adults who know all the warning signs and symptoms for heart attack and stroke tends to be very low. Only 13.6% of adults can identify all the proper heart attack signs and only 22.6% can identify all the proper stroke signs (2007-2009 data).[14] Women tend to be more knowledgeable than men about the signs and symptoms of heart attack and stroke. An estimated 16.4% of females know all heart attack signs compared with about 10.4% of males ($p<0.001$).[14] Also, approximately 23.5% of females know all signs of stroke compared with about 21.4% of males; however, this difference is not statistically significant [Figure 27].[14] Most adults, 91.4%, know that they should call 911 if they thought that someone was having a heart attack or stroke [data not shown].[14]

Figure 27. Age-adjusted Percentage of Connecticut Adults Who Know All the Signs of Heart Attack and Stroke by Gender, 2007-2009, with 95% Confidence Intervals

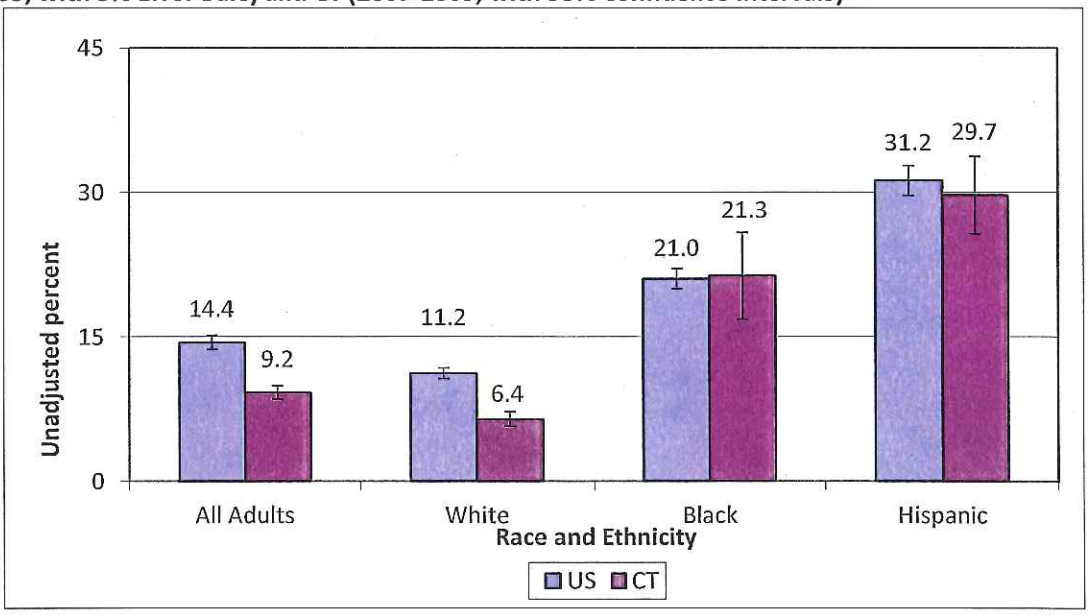


Source: Centers for Disease Control and Prevention, BRFSS, 2010.

ACCESS TO HEALTH CARE

Access to health care is crucial to the prevention, treatment, and management of heart disease and stroke. People without health insurance are less likely than those with health insurance to have a usual source of care, to receive preventive health care services, and to receive appropriate medical management of chronic conditions such as HBP, HBC, and diabetes.[27] About 9% of adults aged 18 and over do not have health insurance (2007-2009 data) compared with approximately 14% of adults nationwide (2009 data).[14, 15] Black and Hispanic Connecticut adults are significantly less likely to have health insurance than White Connecticut adults ($p<0.001$ for both comparisons). Approximately 6% of White, 21% of Black, and 30% of Hispanic adults do not have health insurance.[14] Comparable national figures show that about 11% of White, 21% of Black, and 31% of Hispanic adults report having no health insurance (Figure 28).[15]

Figure 28. Percentage of Adults Who Do Not Have Health Care Coverage by Race and Ethnicity, US (2009, with 5% Error Bars) and CT (2007-2009, with 95% Confidence Intervals)



Source: Centers for Disease Control and Prevention, BRFSS, 2010. Connecticut Department of Public Health, BRFSS, 2010.

TARGETING HIGH-RISK POPULATIONS

The high co-prevalence of modifiable risk factors for CVD indicates the need for public health interventions that focus on the prevention, early detection, and control of modifiable risk factors. The CDC recommends focusing efforts on increasing low dose aspirin therapy according to recognized guidelines; preventing and controlling HBC; reducing sodium intake; preventing and controlling HBC; and increasing the number of smokers counseled to quit and referred to quit lines as well as increasing the availability of no or low-cost cessations products.[28] The CDC also recommends addressing the priority areas through policies, systems, and environmental changes with the potential for broad reach and impact on the general population and high-risk populations.[28]

High-risk populations in Connecticut include Black, Hispanic, and lower-income residents. Black Connecticut residents have higher CVD and stroke mortality rates as well as higher CVD, CHD, and stroke premature mortality rates compared with White Connecticut residents. Black and Hispanic Connecticut residents have significantly higher rates of some important modifiable risk factors for CVD, such as HBC, diabetes, obesity, and physical inactivity compared with White Connecticut residents. Lower-income residents are also more likely to have higher rates of HBC, never having had cholesterol tested, diabetes, current smoking, obesity, and physical inactivity compared with higher-income residents.

Targeted, evidence-based public health interventions are warranted for all Connecticut residents with multiple risk factors. Special emphasis should be placed on interventions that address risk factor reduction among Black, Hispanic, and lower-income Connecticut residents. Evidence-based guidelines for disease prevention in the areas of diabetes, nutrition, physical activity, tobacco, and obesity are provided in the CDC's *Guide to Community Preventive Services*.[29] The 2011 Connecticut Chronic Disease planning process has focused its statewide health promotion and disease prevention efforts on policy, systems, and environmental changes at the state and local levels. Such policy, systems, and environmental changes have the potential to influence health-related behaviors in the general and high-risk populations.

APPENDICES AND REFERENCES

Appendix 1. Data Sources

Connecticut Vital Records Mortality Files

The Connecticut Vital Records Mortality Files are part of the state's vital statistics data base that contains records pertaining to deaths that occur within the state as well as deaths of Connecticut residents occurring in other states, or in Canada. Mortality statistics are compiled in accordance with the World Health Organization (WHO) regulations, which specify that deaths be classified by the current Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Deaths for the 1989-1998 period included in this report are classified by the Ninth Revision of the International Classification of Diseases [ICD-9].[30] Deaths for the 1999-2008 period are classified by the Tenth Revision of the International Classification of Diseases [ICD-10].[31]

The race-ethnicity designation is typically based on report by next of kin, a funeral director, coroner, or other official, often based on observations. As such, the race-ethnicity designation based on observation may be reported incorrectly. Another potential source of error is the fact that death rates are calculated using two different sources of data – the death certificate for the numerator and the U.S. Census Bureau population estimates for the denominator. Errors in under- or over-counting populations by race and/or ethnicity will affect the death rates reported for these groups. Mortality data are reported using racial categories that exclude persons of Hispanic origin (White, non-Hispanic and Black, non-Hispanic) and by Hispanic ethnicity (Hispanics of any race). Death Registry data follow the National Center for Health Statistics guidelines for coding race and Hispanic ethnicity.[5]

Connecticut Hospital Discharge Abstract and Billing Data Base

The Connecticut Hospital Discharge Abstract and Billing Data Base is the source of inpatient hospitalization data. It is maintained by the Connecticut Office of Health Care Access, and it contains patient-level demographic, clinical, and billing data for all non-federal acute care hospitals in the state. In addition to age, gender, and town of residence, the demographic data elements include race and ethnicity. Race and ethnicity may be based upon observation of the patient or self-reporting by the patient. Race is designated as White, non-Hispanic and Black, non-Hispanic; Hispanic ethnicity includes persons of any race.

It should be noted that counts reflect hospitalizations not persons. For example, a patient admitted to a hospital on two separate occasions in 2008 would be counted twice in these data. Another limitation of the data is the fact that it is an administrative data set. It contains diagnoses and procedures based on the International Classification of Diseases, Clinical Modification (ICD-9-CM) codes. The literature contains many reports on the reliability and validity of hospital discharge data with clinical conditions emphasizing discrepancies between ICD-9-CM codes and clinical data.[32]

Behavioral Risk Factor Surveillance System

The Behavioral Risk Factor Surveillance System (BRFSS) survey is a state-based system of health surveys that generate information about health risk behaviors, clinical preventive practices, and health care access and use. The BRFSS, sponsored by the Centers for Disease Control and Prevention, is the world's largest telephone survey, and is conducted in all 50 states. It is an on-going random sample telephone survey of non-institutionalized adults, 18 years and older. Information from the survey is used to improve the health of people nationwide and in Connecticut. Racial and ethnic classifications are based on self-report and include White, non-Hispanic, Black, non-Hispanic, and Hispanic (including persons of any race). Other national and state-specific risk factor data and information regarding BRFSS methodology can be accessed on the CDC's BRFSS Web site at: http://www.cdc.gov/brfss/.

Connecticut School Health Survey

The Connecticut School Health Survey (CSHS) is a comprehensive survey that consists of two components: Youth Tobacco Component (YTC) and the Youth Behavior Component (YBC). The CSHS is conducted by the Connecticut Department of Public Health in cooperation with the CDC, the Connecticut State Department of Education, and partners from local school health districts and local health departments. The YTC is a comprehensive survey of tobacco use, access, cessation, knowledge and attitudes, and exposure among Connecticut students in grades 6-12. The YBC collects data that is used to monitor priority health-risk behaviors and the prevalence of obesity and asthma among high school students in Connecticut. The YBC is administered to a representative sample of all regular public high school students in Connecticut. Racial and ethnic classifications are based on self-report and include White, non-Hispanic; Black, non-Hispanic; and Hispanic (including persons of any race). Further information about the CSHS can be found on the Connecticut Department of Public Health's web site: http://www.ct.gov/dph/cshs. Other national and state-specific youth risk factor data and information can be accessed on the CDC's web site: http://www.cdc.gov/HealthyYouth/YRBS/.

Appendix 2A. ICD-10 Coding for Selected Causes of Death, 1999-2008

Cause of Death	ICD-10 Code
All Causes	A00.0 – Y89.9
All Cancers	C00 – C97
Diabetes Mellitus	E10 – E14
Alzheimer's Disease	G30
Cardiovascular Disease	I00-I78
Diseases of the Heart	I00 – I09, I11, I13, I20 – I51
Coronary Heart Disease	I11, I20-I25
Congestive Heart Failure	I50.0
Essential Hypertension & Hypertensive Renal Disease	I10, I12
Cerebrovascular Disease	I60 – I69
Atherosclerosis	I71
Pneumonia and Influenza	J10 – J18
Chronic Lower Respiratory Diseases	J40 – J47
Unintentional Injuries	V01 – X59, Y85 – Y86

Appendix 2B. ICD-9 Coding for Selected Causes of Death, 1989-1998

Cause of Death	ICD-9 Code
All Causes	1-E999
Cardiovascular Disease Deaths	390-459
Diseases of the Heart	390-398,402,404-429
Coronary Heart Disease	402, 410-414, 429.2
Congestive Heart Failure	428.0
Hypertension without Renal Disease	401, 403
Cerebrovascular Disease	430-438
Atherosclerosis	440

Source: World Health Organization. 1977. Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death, based on the recommendations of the Ninth Revision Conference, 1975 (ICD-9). World Health Organization, Geneva.

Appendix 2C. ICD-9-CM Coding for Selected Causes of Hospitalizations

Cause of Hospitalization	ICD-9-CM Code
Circulatory	390-459
Coronary Heart Disease	402, 410-414, 429.2
Congestive Heart Failure	428
Cerebrovascular Disease	430-438

Appendix 3A. Glossary of Statistical Terms

Age-adjustment. "Age adjustment, using the direct method, is the application of observed age-specific rates to a standard age distribution to eliminate differences in crude rates in populations of interest that result from differences in the populations' age distributions. This adjustment is usually done when comparing two or more populations at one point in time or one population at two or more points in time. Age adjustment is particularly relevant when populations being compared have different age structures, for example, the U.S. white and Hispanic populations...."[33]

Age-adjusted BRFSS rates. Some of the Behavioral Risk Factor Surveillance System (BRFSS) rate estimates presented in this report were age-adjusted, using the direct method, in order to eliminate differences in crude rates in populations of interest that result from differences in the populations' age distributions, such as those of Hispanics and Whites. The following age distributions and age-adjustment weights, based on the 2000 projected U.S. population, were used[34]:

Age Distributions and Age-adjustment Weights, 2000 Projected U.S. Population

Age	Population in thousands	Adjustment weight
18 years and over	203,851	1.000000
18 – 24 years	26,258	0.128810
25 – 44 years	81,892	0.401725
45 – 64 years	60,991	0.299194
65 years and over	34,710	0.170271

Age-adjusted Mortality Rates (AAMR) and Age-adjusted Hospitalization Rates (AAHR) are used to compare relative mortality and hospitalization risk, respectively, across groups and over time. They are not actual measures of risk but rather an index of risk. They are weighted statistical averages of the age-specific rates, in which the weights represent the fixed population proportions by age.[35] The AAMR and AAHR were computed by the direct method. The 1940 and 2000 U.S. standard million population distributions are shown below:

Age group	1940	2000
0-4	80,057	69,136
5-9	81,151	72,533
10-14	89,209	73,032
15-19	93,665	72,169
20-24	88,002	66,477
25-29	84,280	64,529
30-34	77,787	71,044
35-39	72,501	80,762
40-44	66,744	81,851
45-49	62,696	72,118
50-54	55,116	62,716
55-59	44,559	48,454
60-64	36,129	38,793
65-69	28,519	34,264
70-74	19,519	31,773
75-79	11,423	26,999
80-84	5,878	17,842
85+	2,765	15,508
Total	1,000,000	1,000,000

Cause-of-death classification. Mortality statistics for this report were compiled in accordance with the World Health Organization (WHO) regulations, which specify that member nations classify causes of death by the current Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Deaths for the 1989-1998 period were classified by the Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death, Ninth Revision of the International Classification of Diseases (ICD-9).[30] Deaths for the 1999-2008 period were classified according to the Tenth Revision of the International Classification of Diseases (ICD-10).[31]

Healthy People 2010 is part of a national strategy addressing the prevention of major chronic illnesses, injuries, and infectious diseases. It is the product of an effort, involving expert working groups, a consortium of national organizations, all state health departments, and the Institute of Medicine of the National Academy of Sciences to set health objectives for the nation. After extensive national and regional hearings were conducted with a period of public review and comment, the health objectives were published in 1990 as *Healthy People 2000—National Health Promotion and Disease Prevention Objectives.* It established national objectives and served as the basis for the development of state and community plans. *Healthy People 2010* provides a comprehensive view of the nation's health in 2000, and establishes national goals and targets to be achieved by 2010, and monitors progress over time.[36]

Hispanic origin refers to people whose origins are from Spain, the Spanish-speaking countries of Central America, South America, and the Caribbean, or persons of Hispanic origin identifying themselves as Spanish, Spanish-American, Hispanic, Hispano, or Latino. Since 1988, the Connecticut death certificate has had a separate line item for Hispanic ethnicity. Individuals identified as "Hispanic" can be of any race, and are also counted in the race breakdown as either "white," "black," "Asian or Pacific Islander," "American Indian," or other.[5]

International Classification of Diseases 9th and 10th Revisions(ICD-9, ICD-10) have been the internationally accepted coding system for determining cause of death since the early 1900s. It is periodically revised. The Ninth Revision (ICD-9) was in use from 1975 through 1998. Beginning with 1999 deaths, the Tenth Revision (ICD-10) is being used.

Preliminary estimates of the comparability of ICD-9 to ICD-10 have been published and indicate that the discontinuity in trends from 1998 to 1999 for some leading causes of death (septicemia, influenza and pneumonia, Alzheimer's disease, nephritis, nephrotic syndrome, and nephrosis) is substantial.[37]

International Classification of Diseases, Clinical Modification (ICD-9-CM) is a coding system recommended for use in all clinical settings to describe medical procedures and diagnoses. It is required for reporting diagnoses and diseases to all U.S. Public Health Service and Department of Health and Human Services programs, including Medicare and Medicaid. The foundation of the ICD-9-CM is the *International Classification of Diseases, 9th Revision* published by the World Health Organization.[30]

Population bases for computing rates are taken from the U.S. Census Bureau's *Estimates of the population of states by age, sex, race, and Hispanic origin*. These data are estimates of the population of Connecticut by 5-year age groups (age 0 to 4, 5 to 9,...85 and over), sex (male, female), modified race (white; black; Native American including Alaska Natives; Asian and Pacific Islander) and Hispanic origin (Hispanic, non-Hispanic) for each year, July 1, 1999 through July 1, 2009.[5]

Premature mortality. See Years of Potential Life Lost.

Race refers to a population of individuals identified from a common history, nationality, or geographical place. Race is widely considered a valid scientific category, but not a valid biological or genetic category.[38, 39] Available scientific evidence indicates that racial and ethnic classifications do not capture biological distinctiveness, and that there is more genetic variation within racial groups than there is between racial groups.[40, 41] Contemporary race divisions result from historical events and circumstances and reflect current social realities. Thus, racial categories may be viewed more accurately as proxies for social and economic conditions that put individuals at higher risk for certain disease conditions.[32]

Data in this report include two racial groups in Connecticut: white, non-Hispanic and black, non-Hispanic. Individuals identified as "Hispanic" can be of any race.

Socioeconomic position refers to a person's social and economic place in a society, and is operationalized or measured by characteristics such as per capita or household income, educational attainment, or occupation. Historically, lower socioeconomic position has been strongly correlated with less favorable health outcomes such as premature mortality and higher death rates from all causes; conversely, persons of higher socioeconomic position do better on most measures of health status.[12]

Years of potential life lost (YPLL) represents the number of years of potential life lost by each death before a predetermined end point (e.g., 65 or 75 years of age). Whereas the crude and adjusted death rates are heavily influenced by the large number of deaths among the elderly, the YPLL measure provides a picture of premature mortality by weighting deaths that occur at younger ages more heavily than those occurring at older ages, thereby emphasizing different causes of death. Age-adjusted YPLLs are calculated using the methodology of Romeder and McWhinnie.[42] This method consists of a summation of the number of deaths occurring at each age (betweem 1 and 75) multiplied by the remaining years of life had the deceased lived up to age 75.

Appendix 3B. Glossary of Medical Terms

Atherosclerosis: A disease that affects the arteries, particularly those supplying the heart, the brain, the aorta, and the lower extremities. Atherosclerosis underlies the occurrence of heart attacks, many strokes, peripheral arterial disease, and ruptures of the aorta.[43]

Cardiovascular Diseases (CVD): Diseases of the circulatory system, which include acute myocardial infarction, ischemic heart disease, valvular heart disease, peripheral vascular disease, arrhythmias, high blood pressure and stroke.[44]

Coronary Heart Disease (CHD): A form of heart disease resulting from impaired circulation in one or more coronary arteries. Common clinical manifestations of CHD include chest pain (angina pectoris) or "heart attack".[44]

Cerebrovascular Disease: A disease of one or more blood vessels in the brain, which often results in the sudden development of a focal neurologic deficit, or stroke. Stroke, or a "brain attack" is the most severe clinical manifestation of cerebrovascular disease.[1, 45]

Congestive Heart Failure: The inability of the heart to maintain adequate pumping function, which can be caused by a number of factors, such as untreated hypertension, heart attacks, or infections. Heart failure increases the risk for other cardiovascular disease events and often results in physical disability. Congestive Heart Failure is commonly referred to as "heart failure".[43-45]

Diabetes (or diabetes mellitus): A metabolic disorder that results from the body's insufficient production or utilization of insulin. The most common types of diabetes includes "Type 1 diabetes," formerly known as "juvenile diabetes," and "Type 2 diabetes," formerly known as "adult-onset diabetes." Long-term effects of diabetes include cardiovascular complications.[43]

Dyslipidemia: A disorder of lipoprotein metabolism, such as an overproduction or deficiency of lipoprotein. Dyslipidemia is often manifested by elevated levels of total cholesterol, the "bad" or low-density lipoprotein (LDL) cholesterol, and the triglyceride concentrations, as well as decreased levels of the "good" or high-density lipoprotein (HDL) cholesterol concentration in the blood.[46]

Essential Hypertension: high blood pressure without a secondary cause such as renal failure. Approximately 95% of all cases of hypertension are classified as essential hypertension.[47]

Heart Failure: See Congestive Heart Failure.

Hemorrhagic Stroke: Hemorrhagic stroke occurs when a weakened blood vessels ruptures causing bleeding within the brain. The resulting accumulation of blood compresses nearby brain tissue. Hemorrhagic stroke is often associated with high blood pressure. About 13% of all strokes are hemorrhagic.[48]

High Blood Cholesterol: Cholesterol is a substance found in all cells of the body; it is carried in lipoproteins, made of fat (lipid) on the inside and proteins on the outside. Low-density lipoprotein (LDL) cholesterol is sometimes called "bad cholesterol" because it leads to a buildup of cholesterol in arteries. The chance of heart disease increases with increasing LDL levels in the blood. The buildup of cholesterol in the arteries is called plaque, which over time causes the narrowing of the arteries, or "atherosclerosis." Some plaques can burst, releasing fat and cholesterol into the bloodstream, which may cause the blood to clot and block the flow of blood. This blockage can cause angina or a heart attack. Lowering one's cholesterol level decreases the chance of having a plaque burst and a subsequent heart attack. Lowering cholesterol may also slow down, reduce, or even stop plaque from building up.[49]

High Blood Pressure: A condition in which the pressure in the arterial circulation system is greater than clinically recommended, that is a systolic pressure greater than or equal to 140 mm Hg or a diastolic pressure greater than or equal to 90 mm Hg. High blood pressure is associated with increased risk for heart disease, stroke, and chronic kidney disease.[43]

Hypertensive Heart Disease: An abnormality in the structure and function of the heart caused by long-standing high blood pressure. A common, clinical manifestation of hypertensive heart disease is heart failure.[43]

Ischemic Heart Disease: A condition in which heart muscle is damaged or works inefficiently because of an absence or deficiency of its blood supply. Ischemic heart disease is most often caused by atherosclerosis, and includes angina pectoris, acute myocardial infarction, chronic ischemic heart disease, and sudden death.[44]

Ischemic Stroke: The most common type of stroke that results from an obstruction within a blood vessel supplying blood to the brain. Atherosclerosis is the cause of the obstruction. About 87% of strokes are ischemic strokes.[50]

Obesity: Defined in terms of body mass index (BMI), and calculated as body weight in kilograms (1 kg = 2.2 lbs.) divided by height in meters (1 m = 39.37 in) squared. Adults with a BMI of greater than or equal to 30.0 kg/m2 are considered "obese," and those with a BMI of 25–29.9 kg/m2 are considered "overweight".[43]

Classification of Overweight and Obesity in Adults According to BMI.[44] Obesity is classified as BMI $\geq$ 30 kg/m^2.		
Classification	**BMI (kg/m^2)**	**Risk of Health Problems**
Underweight	< 18.5	Low (but risk of other clinical problems increased)
Normal range	18.5-24.9	Average
Overweight	25.0-29.9	Mildly increased
Obese	**> 30.0**	
Class I	30.0-34.9	Moderate
Class II	35.0-39.9	Severe
Class III	> 40.0	Very severe
Note that these values are age-independent and correspond to the same degree of fatness across different populations.		

Serum (Blood) Lipids: Cholesterol and triglycerides are types of lipids circulating in the blood. Over time, elevated cholesterol and triglycerides in the blood can become plaque in artery walls leading to atherosclerosis. Elevated cholesterol and triglyceride levels are often found in individuals with other major risk factors for heart disease (obesity, diabetes, and/or high blood pressure).[51]

Stroke: The most common clinical manifestation of cerebrovascular disease. Stroke describes an interruption of the blood supply in the brain that results in damaged brain tissue. It can be caused by clots or by bleeding in the brain from a ruptured blood vessel or a significant injury.[1, 52]

Lisa Davis
Deputy Commissioner
Office of Health Care Access
Department of Public Health
410 Capitol Avenue, MS#13HCA
P.O. Box 340308
Hartford, CT 06134

Dear Deputy Commissioner Davis:

I am writing this letter to express my support for the proposed elective angioplasty program at Greenwich Hospital as a satellite of the Yale-New Haven Heart and Vascular Center. Since the inception of the primary angioplasty program at Greenwich Hospital, I have been the Medical Director overseeing its daily operation. This program has demonstrated success and has saved lives in the community. The excellent outcomes and safety we have demonstrated with the primary angioplasty program puts us in a unique position to expand our access of high quality care to patients of this community and offer them elective angioplasty at Greenwich Hospital.

We are seeking to build on the unique structure that is already in place at Greenwich Hospital. It is cost effective and efficient to use what is already available for *emergency* angioplasty patients to also provide care to *elective* angioplasty patients. An elective angioplasty program will improve access to care locally. Patient and family satisfaction will improve as Greenwich Hospital patients will no longer have to transfer out of the region despite the availability of equipment and facilities, qualified staff and high volume operators. Currently, the transfer of patients out of the region produces an emotional, financial and occasionally physical hardship on patients and their families.

The elective angioplasty program at Greenwich Hospital would adhere to the standards set forth by the Yale-New Haven Heart and Vascular Center. We will continue the current comprehensive quality and outcome monitoring that we have created for our primary angioplasty program. Approval of an elective angioplasty program at Greenwich Hospital will improve the overall quality of the Greenwich Hospital cardiology program as it will provide the staff and operators with greater number of patients with a broader spectrum of disease to maintain competency and high quality standards.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Christopher J. Howes, MD

Dear Deputy Commissioner Davis:

I am writing this letter to express my support for the proposed elective angioplasty program at Greenwich Hospital as a satellite of the Yale-New Haven Heart and Vascular Center. As Clinical Chief of Cardiology for Yale School of Medicine and Medical Director of the Yale-New Haven Heart and Vascular Center, I have played a key role in the implementation of the primary angioplasty program at Greenwich Hospital. This program has demonstrated success and has saved lives in the community. We are seeking to build on the unique structure that is already in place at Greenwich Hospital. This program will improve continuity of care as Greenwich Hospital patients now must be transferred for elective angioplasty despite the availability of equipment and facilities, qualified staff and high volume operators.

The program will be supervised and directed by the Yale Interventional Group and all procedures will be performed by highly qualified physicians. The elective angioplasty program at Greenwich Hospital would adhere to the high standards set forth by the Yale-New Haven Heart and Vascular Center. Quality and outcomes monitoring would be provided by the Yale-New Haven Heart and Vascular Center. The facility, physicians, staff and equipment required to perform elective angioplasty services are already in place at Greenwich Hospital. It is cost effective and efficient to use what is already available for *emergency* angioplasty patients to also provide care to *elective* angioplasty patients.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Henry S. Cabin, MD
Clinical Chief of Cardiology,
Yale School of Medicine

Hartford, CT 06134

Dear Deputy Commissioner Davis:

I am writing this letter in support of Greenwich Hospital's application to provide elective angioplasty to the communities it serves. I am the Chief Medical Officer for WESTMED Medical Group, a large multi-specialty group of over 200 physicians with locations throughout Westchester County, New York. Many of our cardiologists are on the medical staff at Greenwich Hospital. It is our experience that our patients in the Greenwich Hospital service area use the Hospital's services for their health care needs including cardiac services. If Greenwich Hospital offered elective angioplasty, we feel confident that these patients would prefer the convenient location of Greenwich Hospital along with the high quality and competent physicians and staff, up-to-date facilities and appropriate safety measures in place at the Hospital.

An elective angioplasty service at Greenwich Hospital will provide cardiac patients with local access to high quality interventional cardiology services. Patients from the Greenwich Hospital service area that need elective angioplasty are currently required to go to another hospital to receive these services since Greenwich Hospital is not approved to provide elective angioplasty services. However, the same facility, physicians, staff and equipment required to perform *elective* angioplasty services are already in place for Greenwich Hospital's approved *emergency* angioplasty program. This is a more cost effective use of resources. In addition, the ability to provide elective angioplasty will improve the continuity of care available to patients at Greenwich Hospital.

Thank you for your consideration of the Greenwich Hospital application to add elective angioplasty to the continuum of cardiac services already provided by the Hospital.

I urge you to approve this application.

Sincerely,

Barney D. Newman MD

PREAMBLE

The medical profession should play a central role in evaluating the evidence related to drugs, devices, and procedures for the detection, management, and prevention of disease. When properly applied, expert analysis of available data on the benefits and risks of these therapies and procedures can improve the quality of care, optimize patient outcomes, and favorably affect costs by focusing resources on the most effective strategies. An organized and directed approach to a thorough review of evidence has resulted in the production of clinical practice guidelines that assist physicians in selecting the best management strategy for an individual patient. Moreover, clinical practice guidelines can provide a foundation for other applications, such as performance measures, appropriate use criteria, and both quality improvement and clinical decision support tools.

The American College of Cardiology Foundation (ACCF) and the American Heart Association (AHA) have jointly produced guidelines in the area of cardiovascular disease since 1980. The ACCF/AHA Task Force on Practice Guidelines (Task Force), charged with developing, updating, and revising practice guidelines for cardiovascular diseases and procedures, directs and oversees this effort. Writing committees are charged with regularly reviewing and evaluating all available evidence to develop balanced, patient-centric recommendations for clinical practice.

Experts in the subject under consideration are selected by the ACCF and AHA to examine subject-specific data and write guidelines in partnership with representatives from other medical organizations and specialty groups. Writing committees are asked to perform a formal literature review; weigh the strength of evidence for or against particular tests, treatments, or procedures; and include estimates of expected outcomes where such data exist. Patient-specific modifiers, comorbidities, and issues of patient preference that may influence the choice of tests or therapies are considered. When available, information from studies on cost is considered, but data on efficacy and outcomes constitute the primary basis for the recommendations contained herein.

In analyzing the data and developing recommendations and supporting text, the writing committee uses evidence-based methodologies developed by the Task Force (1). The Class of Recommendation (COR) is an estimate of the size of the treatment effect considering risks versus benefits in addition to evidence and/or agreement that a given treatment or procedure is or is not useful/effective or in some situations may cause harm. The Level of Evidence (LOE) is an estimate of the certainty or precision of the treatment effect. The writing committee reviews and ranks evidence supporting each recommendation with the weight of evidence ranked as LOE A, B, or C according to specific definitions that are included in Table 1. Studies are identified as observational, retrospective, prospective, or randomized where appropriate. For certain conditions for which inadequate data are available, recommendations are based on expert consensus and clinical experience and are ranked as LOE C. When recommendations at LOE C are supported by historical clinical data, appropriate references (including clinical reviews) are cited if available. For issues for which sparse data are available, a survey of current practice among the clinicians on the writing committee is the basis for LOE C recommendations and no references are cited. The schema for COR and LOE is summarized in Table 1, which also provides suggested phrases for writing recommendations within each COR. A new addition to this methodology is separation of the Class III recommendations to delineate if the recommendation is determined to be of "no benefit" or is associated with "harm" to the patient. In addition, in view of the increasing number of comparative effectiveness studies, comparator verbs and suggested phrases for writing recommendations for the comparative effectiveness of one treatment or strategy versus another have been added for COR I and IIa, LOE A or B only. T1

TABLE 1. Applying Classification of Recommendations and Level of Evidence

ESTIMATE OF CERTAINTY (PRECISION) OF TREATMENT EFFECT	CLASS I *Benefit >>> Risk* Procedure/Treatment **SHOULD** be performed/ administered	CLASS IIa *Benefit >> Risk* *Additional studies with focused objectives needed* **IT IS REASONABLE** to perform procedure/administer treatment	CLASS IIb *Benefit ≥ Risk* *Additional studies with broad objectives needed; additional registry data would be helpful* Procedure/Treatment **MAY BE CONSIDERED**	CLASS III *No Benefit* or CLASS III *Harm* COR III: No benefit — Procedure/Test: Not Helpful; Treatment: No Proven Benefit COR III: Harm — Procedure/Test: Excess Cost w/o Benefit or Harmful; Treatment: Harmful to Patients
LEVEL A Multiple populations evaluated* Data derived from multiple randomized clinical trials or meta-analyses	■ Recommendation that procedure or treatment is useful/effective ■ Sufficient evidence from multiple randomized trials or meta-analyses	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Sufficient evidence from multiple randomized trials or meta-analyses
LEVEL B Limited populations evaluated* Data derived from a single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is useful/effective ■ Evidence from single randomized trial or nonrandomized studies	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Evidence from single randomized trial or nonrandomized studies
LEVEL C Very limited populations evaluated* Only consensus opinion of experts, case studies, or standard of care	■ Recommendation that procedure or treatment is useful/effective ■ Only expert opinion, case studies, or standard of care	■ Recommendation in favor of treatment or procedure being useful/effective ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation's usefulness/efficacy less well established ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Only expert opinion, case studies, or standard of care
Suggested phrases for writing recommendations	should is recommended is indicated is useful/effective/beneficial	is reasonable can be useful/effective/beneficial is probably recommended or indicated	may/might be considered may/might be reasonable usefulness/effectiveness is unknown/unclear/uncertain or not well established	COR III: No Benefit — is not recommended; is not indicated; should not be performed/ administered/ other; is not useful/ beneficial/ effective COR III: Harm — potentially harmful; causes harm; associated with excess morbidity/mortality; should not be performed/ administered/ other
Comparative effectiveness phrases†	treatment/strategy A is recommended/indicated in preference to treatment B treatment A should be chosen over treatment B	treatment/strategy A is probably recommended/indicated in preference to treatment B it is reasonable to choose treatment A over treatment B		

A recommendation with Level of Evidence B or C does not imply that the recommendation is weak. Many important clinical questions addressed in the guidelines do not lend themselves to clinical trials. Although randomized trials are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

*Data available from clinical trials or registries about the usefulness/efficacy in different subpopulations, such as sex, age, history of diabetes, history of prior myocardial infarction, history of heart failure, and prior aspirin use. †For comparative effectiveness recommendations (Class I and IIa; Level of Evidence A and B only), studies that support the use of comparator verbs should involve direct comparisons of the treatments or strategies being evaluated.

In view of the advances in medical therapy across the spectrum of cardiovascular diseases, the Task Force has designated the term *guideline-directed medical therapy (GDMT)* to represent optimal medical therapy as defined by ACCF/AHA guideline recommended therapies (primarily Class I). This new term, GDMT, will be used herein and throughout all future guidelines.

Because the ACCF/AHA practice guidelines address patient populations (and healthcare providers) residing in North America, drugs that are not currently available in North America are discussed in the text without a specific COR. For studies performed in large numbers of subjects outside North America, each writing committee reviews the potential influence of different practice patterns and patient populations on the treatment effect and relevance to the ACCF/AHA target population to determine whether the findings should inform a specific recommendation.

The ACCF/AHA practice guidelines are intended to assist healthcare providers in clinical decision making by describing a range of generally acceptable

ID: kandasamy.d | Black Lining: [ON] | Time: 12:16 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

approaches to the diagnosis, management, and prevention of specific diseases or conditions. The guidelines attempt to define practices that meet the needs of most patients in most circumstances. The ultimate judgment regarding care of a particular patient must be made by the healthcare provider and patient in light of all the circumstances presented by that patient. As a result, situations may arise for which deviations from these guidelines may be appropriate. Clinical decision making should involve consideration of the quality and availability of expertise in the area where care is provided. When these guidelines are used as the basis for regulatory or payer decisions, the goal should be improvement in quality of care. The Task Force recognizes that situations arise in which additional data are needed to inform patient care more effectively; these areas will be identified within each respective guideline when appropriate.

Prescribed courses of treatment in accordance with these recommendations are effective only if followed. Because lack of patient understanding and adherence may adversely affect outcomes, physicians and other healthcare providers should make every effort to engage the patient's active participation in prescribed medical regimens and lifestyles. In addition, patients should be informed of the risks, benefits, and alternatives to a particular treatment and be involved in shared decision making whenever feasible, particularly for COR IIa and IIb, where the benefit-to-risk ratio may be lower.

The Task Force makes every effort to avoid actual, potential, or perceived conflicts of interest that may arise as a result of industry relationships or personal interests among the members of the writing committee. All writing committee members and peer reviewers of the guideline are asked to disclose all such current relationships, as well as those existing 12 months previously. In December 2009, the ACCF and AHA implemented a new policy for relationships with industry and other entities (RWI) that requires the writing committee chair plus a minimum of 50% of the writing committee to have no *relevant* RWI (Appendix 1 for the ACCF/AHA definition of relevance). These statements are reviewed by the Task Force and all members during each conference call and/or meeting of the writing committee and are updated as changes occur. All guideline recommendations require a confidential vote by the writing committee and must be approved by a consensus of the voting members. Members are not permitted to write, and must recuse themselves from voting on, any recommendation or section to which their RWI apply. Members who recused themselves from voting are indicated in the list of writing committee members, and section recusals are noted in Appendix 1. Authors' and peer reviewers' RWI pertinent to this guideline are disclosed in Appendixes 1 and 2, respectively. Additionally, to ensure complete transparency, writing committee members' comprehensive disclosure information—including RWI not pertinent to this document—is available as an online supplement. Comprehensive disclosure information for the Task Force is also available online at www.cardiosource.org/ACC/ About-ACC/Leadership/Guidelines-and-Documents-Task-Forces.aspx. The work of the writing committee was supported exclusively by the ACCF, AHA, and the Society for Cardiovascular Angiography and Interventions (SCAI) without commercial support. Writing committee members volunteered their time for this activity.

In an effort to maintain relevance at the point of care for practicing physicians, the Task Force continues to oversee an ongoing process improvement initiative. As a result, in response to pilot projects, several changes to these guidelines will be apparent, including limited narrative text, a focus on summary and evidence tables (with references linked to abstracts in PubMed) and more liberal use of summary recommendation tables (with references that support LOE) to serve as a quick reference.

In April 2011, the Institute of Medicine released 2 reports: *Finding What Works in Health Care: Standards for Systematic Reviews* and *Clinical Practice Guidelines We Can Trust* (2, 3). It is noteworthy that the ACCF/AHA guidelines were cited as being compliant with many of the standards that were proposed. A thorough review of these reports and of our current methodology is under way, with further enhancements anticipated.

The recommendations in this guideline are considered current until they are superseded by a focused update or the full-text guideline is revised. Guidelines are official policy of both the ACCF and AHA.

Alice K. Jacobs, MD, FACC, FAHA, Chair
ACCF/AHA Task Force on Practice Guidelines

1. INTRODUCTION

1.1. Methodology and Evidence Review

The recommendations listed in this document are, whenever possible, evidence based. An extensive evidence review was conducted through November 2010, as well as selected other references through August 2011. Searches were limited to studies, reviews, and other evidence conducted in human subjects and that were published in English. Key search words included but were not limited to the following: *ad hoc angioplasty, angioplasty, balloon angioplasty, clinical trial, coronary stenting, delayed angioplasty, meta-analysis,*

percutaneous transluminal coronary angioplasty, randomized controlled trial (RCT), percutaneous coronary intervention (PCI) and angina, angina reduction, antiplatelet therapy, bare-metal stents (BMS), cardiac rehabilitation, chronic stable angina, complication, coronary bifurcation lesion, coronary calcified lesion, coronary chronic total occlusion (CTO), coronary ostial lesions, coronary stent (BMS and drug-eluting stents [DES]; and BMS versus DES), diabetes, distal embolization, distal protection, elderly, ethics, late stent thrombosis, medical therapy, microembolization, mortality, multiple lesions, multi-vessel, myocardial infarction (MI), non—ST-elevation myocardial infarction (NSTEMI), no-reflow, optical coherence tomography, proton pump inhibitor (PPI), return to work, same-day angioplasty and/or stenting, slow flow, stable ischemic heart disease (SIHD), staged angioplasty, STEMI, survival, and *unstable angina (UA)*. Additional searches cross-referenced these topics with the following subtopics: *anticoagulant therapy, contrast nephropathy, PCI-related vascular complications, unprotected left main PCI, multivessel coronary artery disease (CAD), adjunctive percutaneous interventional devices, percutaneous hemodynamic support devices*, and *secondary prevention*. Additionally, the committee reviewed documents related to the subject matter previously published by the ACCF and AHA. References selected and published in this document are representative and not all-inclusive.

To provide clinicians with a comprehensive set of data, whenever deemed appropriate or when published, the absolute risk difference and number needed to treat or harm will be provided in the guideline, along with confidence intervals (CIs) and data related to the relative treatment effects such as odds ratio (OR), relative risk, hazard ratio (HR), or incidence rate ratio.

The focus of this guideline is the safe, appropriate, and efficacious performance of PCI. The risks of PCI must be balanced against the likelihood of improved survival, symptoms, or functional status. This is especially important in patients with SIHD.

1.2. Organization of the Writing Committee

The committee was composed of physicians with expertise in interventional cardiology, general cardiology, critical care cardiology, cardiothoracic surgery, clinical trials, and health services research. The committee included representatives from the ACCF, AHA, and SCAI.

1.3. Document Review and Approval

This document was reviewed by 2 official reviewers nominated by the ACCF, AHA, and SCAI, as well as 21 individual content reviewers (including members of the ACCF Interventional Scientific Council and ACCF Surgeons' Scientific Council). All information on reviewers' RWI was distributed to the writing committee and is published in this document (Appendix 2). This document was approved for publication by the governing bodies of the ACCF, AHA, and SCAI.

1.4. PCI Guidelines: History and Evolution

In 1982, a 2-page manuscript titled "Guidelines for the Performance of Percutaneous Transluminal Coronary Angioplasty" was published in *Circulation* (4). The document, which addressed the specific expertise and experience physicians should have to perform balloon angioplasty, as well as laboratory requirements and the need for surgical support, was written by an ad hoc group whose members included Andreas Grüntzig. In 1980, the ACC and the AHA established the Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures, which was charged with the development of guidelines related to the role of new therapeutic approaches and of specific noninvasive and invasive procedures in the diagnosis and management of cardiovascular disease. The first ACC/ AHA Task Force report on guidelines for coronary balloon angioplasty was published in 1988 (5). The 18-page document discussed and made recommendations about lesion classification and success rates, indications for and contraindications to balloon angioplasty, institutional review of angioplasty procedures, ad hoc angioplasty after angiography, and on-site surgical backup. Further iterations of the guidelines were published in 1993 (6), 2001 (7), and 2005 (8). In 2007 and 2009, focused updates to the guideline were published to expeditiously address new study results and recent changes in the field of interventional cardiology (9, 10). The 2009 focused update is notable in that there was direct collaboration between the writing committees for the STEMI guidelines and the PCI guidelines, resulting in a single publication of focused updates on STEMI and PCI (10).

The evolution of the PCI guideline reflects the growth of knowledge in the field and parallels the many advances and innovations in the field of interventional cardiology, including primary PCI, BMS and DES, intravascular ultrasound (IVUS) and physiologic assessments of stenosis, and newer antiplatelet and anticoagulant therapies. The 2011 iteration of the guideline continues this process, addressing ethical aspects of PCI, vascular access considerations, CAD revascularization including hybrid revascularization, revascularization before noncardiac surgery, optical coherence tomography, advanced hemodynamic support

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

devices, no-reflow therapies, and vascular closure devices. Most of this document is organized according to "patient flow," consisting of preprocedural considerations, procedural considerations, and postprocedural considerations. In a major undertaking, the STEMI, PCI, and coronary artery bypass graft (CABG) surgery guidelines were written concurrently, with additional collaboration with the SIHD guideline writing committee, allowing greater collaboration between the different writing committees on topics such as PCI in STEMI and revascularization strategies in patients with CAD (including unprotected left main PCI, multivessel disease revascularization, and hybrid procedures).

In accordance with direction from the Task Force and feedback from readers, in this iteration of the guideline, the text has been shortened, with an emphasis on summary statements rather than detailed discussion of numerous individual trials. Online supplemental evidence and summary tables have been created to document the studies and data considered for new or changed guideline recommendations.

2. CAD REVASCULARIZATION

Recommendations and text in this section are the result of extensive collaborative discussions between the PCI and CABG writing committees, as well as key members of the SIHD and UA/NSTEMI writing committees. Certain issues, such as older versus more contemporary studies, primary analyses versus subgroup analyses, and prospective versus post hoc analyses, have been carefully weighed in designating COR and LOE; they are addressed in the appropriate corresponding text. The goals of revascularization for patients with CAD are to 1) improve survival and/or 2) relieve symptoms.

Revascularization recommendations in this section are predominantly based on studies of patients with symptomatic SIHD and should be interpreted in this context. As discussed later in this section, recommendations on the type of revascularization are, in general, applicable to patients with UA/NSTEMI. In some cases (e.g., unprotected left main CAD), specific recommendations are made for patients with UA/NSTEMI or STEMI.

Historically, most studies of revascularization have been based on and reported according to angiographic criteria. Most studies have defined a "significant" stenosis as $\geq$ 70% diameter narrowing; therefore, for revascularization decisions and recommendations in this section, a "significant" stenosis has been defined as $\geq$ 70% diameter narrowing ($\geq$50% for left main CAD). Physiological criteria, such as an assessment of fractional flow reserve (FFR), has been used in deciding when revascularization is indicated. Thus, for recommendations about revascularization in this section, coronary stenoses with FFR $\leq$ 0.80 can also be considered to be "significant" (11, 12).

As noted, the revascularization recommendations have been formulated to address issues related to 1) improved survival and/or 2) improved symptoms. When one method of revascularization is preferred over the other for improved survival, this consideration, in general, takes precedence over improved symptoms. When discussing options for revascularization with the patient, he or she should understand when the procedure is being performed in an attempt to improve symptoms, survival, or both.

Although some results from the SYNTAX (Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery) study are best characterized as subgroup analyses and "hypothesis generating," SYNTAX nonetheless represents the latest and most comprehensive comparison of PCI and CABG (13, 14). Therefore, the results of SYNTAX have been considered appropriately when formulating our revascularization recommendations. Although the limitations of using the SYNTAX score for certain revascularization recommendations are recognized, the SYNTAX score is a reasonable surrogate for the extent of CAD and its complexity and serves as important information that should be considered when making revascularization decisions. Recommendations that refer to SYNTAX scores use them as surrogates for the extent and complexity of CAD.

Revascularization recommendations to improve survival and symptoms are provided in the following text and are summarized in Tables 2 and 3. References to studies comparing revascularization with medical therapy are presented when available for each anatomic subgroup. T2 T3

See Online Data Supplements 1 and 2 for additional data regarding the survival and symptomatic benefits with CABG or PCI for different anatomic subsets.

2.1. Heart Team Approach to Revascularization Decisions: Recommendations

CLASS I

1. A Heart Team approach to revascularization is recommended in patients with unprotected left main or complex CAD (14–16). *(Level of Evidence: C)*

CLASS IIa

1. Calculation of the Society of Thoracic Surgeons (STS) and SYNTAX scores is reasonable in patients with unprotected left main and complex CAD (13, 14, 17–22). *(Level of Evidence: B)*

One protocol used in RCTs (14–16, 23) often involves a multidisciplinary approach referred to as the Heart Team. Composed of an interventional cardiologist and a cardiac surgeon, the Heart Team 1) reviews the patient's medical condition and coronary anatomy, 2) determines that PCI and/or CABG are technically feasible and reasonable, and 3) discusses revascularization options with the patient before a treatment strategy is selected. Support for using a Heart Team approach comes from reports that patients with complex CAD referred specifically for PCI or CABG in concurrent trial registries have lower mortality rates than those randomly assigned to PCI or CABG in controlled trials (15, 16).

The SIHD, PCI, and CABG guideline writing committees endorse a Heart Team approach in patients with unprotected left main CAD and/or complex CAD in whom the optimal revascularization strategy is not straightforward. A collaborative assessment of revascularization options, or the decision to treat with GDMT without revascularization, involving an interventional cardiologist, a cardiac surgeon, and (often) the patient's general cardiologist, followed by discussion with the patient about treatment options, is optimal. Particularly in patients with SIHD and unprotected left main and/or complex CAD for whom a revascularization strategy is not straightforward, an approach has been endorsed that involves terminating the procedure after diagnostic coronary angiography is completed: this allows a thorough discussion and affords both the interventional cardiologist and cardiac surgeon the opportunity to discuss revascularization options with the patient. Because the STS score and the SYNTAX score have been shown to predict adverse outcomes in patients undergoing CABG and PCI, respectively, calculation of these scores is often useful in making revascularization decisions (13, 14, 17–22).

2.2. Revascularization to Improve Survival: Recommendations

Left Main CAD Revascularization

CLASS I

1. CABG to improve survival is recommended for patients with significant (≥50% diameter stenosis) left main coronary artery stenosis (24–30). *(Level of Evidence: B)*

CLASS IIa

1. PCI to improve survival is reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: 1) anatomic conditions associated with a low risk of PCI procedural complications and a high likelihood of good long-term outcome (e.g., a low SYNTAX score [≤22], ostial or trunk left main CAD); and 2) clinical characteristics that predict a significantly increased risk of adverse surgical outcomes (e.g., STS-predicted risk of operative mortality ≥5%) (13, 17, 19, 23, 31–48). *(Level of Evidence: B)*
2. PCI to improve survival is reasonable in patients with UA/NSTEMI when an unprotected left main coronary artery is the culprit lesion and the patient is not a candidate for CABG (13, 36–39, 44, 45, 47–49). *(Level of Evidence: B)*
3. PCI to improve survival is reasonable in patients with acute STEMI when an unprotected left main coronary artery is the culprit lesion, distal coronary flow is less than TIMI (Thrombolysis In Myocardial Infarction) grade 3, and PCI can be performed more rapidly and safely than CABG (33, 50, 51). *(Level of Evidence: C)*

CLASS IIb

1. PCI to improve survival may be reasonable as an alternative to CABG in selected stable patients with significant (≥50% diameter stenosis) unprotected left main CAD with: 1) anatomic conditions associated with a low to intermediate risk of PCI procedural complications and an intermediate to high likelihood of good long-term outcome (e.g., low-intermediate SYNTAX score of <33, bifurcation left main CAD); and 2) clinical characteristics that predict an increased risk of adverse surgical outcomes (e.g., moderate-severe chronic obstructive pulmonary disease, disability from previous stroke, or previous cardiac surgery; STS-predicted risk of operative mortality >2%) (13, 17, 19, 23, 31–48, 52). *(Level of Evidence: B)*

CLASS III: HARM

1. PCI to improve survival should not be performed in stable patients with significant (≥50% diameter stenosis) unprotected left main CAD who have unfavorable anatomy for PCI and who are good candidates for CABG (13, 17, 19, 24–32). *(Level of Evidence: B)*

Non-Left Main CAD Revascularization

CLASS I

1. CABG to improve survival is beneficial in patients with significant (≥70% diameter) stenoses in 3 major coronary arteries (with or without involvement of the proximal left anterior descending [LAD] artery) or in the proximal LAD plus 1 other major coronary artery (26, 30, 53–56). *(Level of Evidence: B)*

No anatomic or physiologic criteria for revascularization	III: Harm–CABG III: Harm–PCI	C	N/A

CABG indicates coronary artery bypass graft; CAD, coronary artery disease; COR, class of recommendation; FFR, fractional flow reserve; GDMT, guideline-directed medical therapy; LOE, level of evidence; N/A, not applicable; PCI, percutaneous coronary intervention; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery; and TMR, transmyocardial laser revascularization.

2. CABG or PCI to improve survival is beneficial in survivors of sudden cardiac death with presumed ischemia-mediated ventricular tachycardia caused by significant (≥70% diameter) stenosis in a major coronary artery. *(CABG Level of Evidence: B* [57–59]; *PCI Level of Evidence: C* [57])

CLASS IIa

1. CABG to improve survival is reasonable in patients with significant (≥70% diameter) stenoses in 2 major coronary arteries with severe or extensive myocardial ischemia (e.g., high-risk criteria on stress testing, abnormal intracoronary hemodynamic evaluation, or >20% perfusion defect by myocardial perfusion stress imaging) or target vessels supplying a large area of viable myocardium (60–63). *(Level of Evidence: B)*
2. CABG to improve survival is reasonable in patients with mild-moderate left ventricular (LV) systolic dysfunction (ejection fraction [EF] 35% to 50%) and significant (≥70% diameter stenosis) multi-vessel CAD or proximal LAD coronary artery stenosis, when viable myocardium is present in the region of intended revascularization (30, 64–68). *(Level of Evidence: B)*
3. CABG with a left internal mammary artery (LIMA) graft to improve survival is reasonable in patients with significant (≥70% diameter) stenosis in the proximal LAD artery and evidence of extensive ischemia (30, 56, 69, 70). *(Level of Evidence: B)*
4. It is reasonable to choose CABG over PCI to improve survival in patients with complex 3-vessel CAD (e.g., SYNTAX score >22), with or without involvement of the proximal LAD artery who are good candidates for CABG (32, 46, 56, 71, 72). *(Level of Evidence: B)*
5. CABG is probably recommended in preference to PCI to improve survival in patients with multivessel CAD and diabetes mellitus, particularly if a LIMA graft can be anastomosed to the LAD artery (62, 74–81). *(Level of Evidence: B)*

CLASS IIb

1. The usefulness of CABG to improve survival is uncertain in patients with significant (≥70%) diameter stenoses in 2 major coronary arteries not involving the proximal LAD artery and without extensive ischemia (56). *(Level of Evidence: C)*
2. The usefulness of PCI to improve survival is uncertain in patients with 2- or 3-vessel CAD (with or without involvement of the proximal LAD artery) or 1-vessel proximal LAD disease (26, 53, 56, 82). *(Level of Evidence: B)*
3. CABG might be considered with the primary or sole intent of improving survival in patients with SIHD with severe LV systolic dysfunction (EF <35%) whether or not viable myocardium is present (30, 64–68, 83, 84). *(Level of Evidence: B)*
4. The usefulness of CABG or PCI to improve survival is uncertain in patients with previous CABG and extensive anterior wall ischemia on noninvasive testing (85–93). *(Level of Evidence: B)*

CLASS III: HARM

1. CABG or PCI should not be performed with the primary or sole intent to improve survival in patients with SIHD with 1 or more coronary stenoses that

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

are not anatomically or functionally significant (e.g., <70% diameter non-left main coronary artery stenosis, FFR >0.80, no or only mild ischemia on noninvasive testing), involve only the left circumflex or right coronary artery, or subtend only a small area of viable myocardium (30, 53, 60, 61, 94–98). *(Level of Evidence: B)*

2.3. Revascularization to Improve Symptoms: Recommendations

CLASS I

1. CABG or PCI to improve symptoms is beneficial in patients with 1 or more significant (≥70% diameter) coronary artery stenoses amenable to revascularization and unacceptable angina despite GDMT (82, 99–108). *(Level of Evidence: A)*

CLASS IIa

1. CABG or PCI to improve symptoms is reasonable in patients with 1 or more significant (≥70% diameter) coronary artery stenoses and unacceptable angina for whom GDMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences. *(Level of Evidence: C)*
2. PCI to improve symptoms is reasonable in patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses associated with ischemia, and unacceptable angina despite GDMT (86, 89, 92). *(Level of Evidence: C)*
3. It is reasonable to choose CABG over PCI to improve symptoms in patients with complex 3-vessel CAD (e.g., SYNTAX score >22), with or without involvement of the proximal LAD artery who are good candidates for CABG (32, 46, 56, 72, 73). *(Level of Evidence: B)*

CLASS IIb

1. CABG to improve symptoms might be reasonable for patients with previous CABG, 1 or more significant (≥70% diameter) coronary artery stenoses not amenable to PCI, and unacceptable angina despite GDMT (93). *(Level of Evidence: C)*
2. Transmyocardial laser revascularization (TMR) performed as an adjunct to CABG to improve symptoms may be reasonable in patients with viable ischemic myocardium that is perfused by arteries that are not amenable to grafting (109–113). *(Level of Evidence: B)*

CLASS III: HARM

1. CABG or PCI to improve symptoms should not be performed in patients who do not meet anatomic (≥50% diameter left main or ≥70% non-left main stenosis diameter) or physiological (e.g., abnormal FFR) criteria for revascularization. *(Level of Evidence: C)*

2.4. CABG Versus Contemporaneous Medical Therapy

In the 1970s and 1980s, 3 RCTs established the survival benefit of CABG compared with contemporaneous (although minimal by current standards) medical therapy without revascularization in certain subjects with stable angina: the Veterans Affairs Cooperative Study (114), European Coronary Surgery Study (55), and CASS (Coronary Artery Surgery Study) (115). Subsequently, a 1994 meta-analysis of 7 studies that randomized a total of 2,649 patients to medical therapy or CABG (30) showed that CABG offered a survival advantage over medical therapy for patients with left main or 3-vessel CAD. The studies also established that CABG is more effective than medical therapy for relieving anginal symptoms. These studies have been replicated only once during the past decade. In MASS II (Medicine, Angioplasty, or Surgery Study II), patients with multivessel CAD who were treated with CABG were less likely than those treated with medical therapy to have a subsequent MI, need additional revascularization, or experience cardiac death in the 10 years after randomization (104).

Surgical techniques and medical therapy have improved substantially during the intervening years. As a result, if CABG were to be compared with GDMT in RCTs today, the relative benefits for survival and angina relief observed several decades ago might no longer be observed. Conversely, the concurrent administration of GDMT may substantially improve long-term outcomes in patients treated with CABG in comparison with those receiving medical therapy alone. In the BARI 2D (Bypass Angioplasty Revascularization Investigation 2 Diabetes) trial of patients with diabetes mellitus, no significant difference in risk of mortality in the cohort of patients randomized to GDMT plus CABG or GDMT alone was observed, although the study was not powered for this endpoint, excluded patients with significant left main CAD, and included only a small percentage of patients with proximal LAD artery disease or LV ejection fraction (LVEF) <0.50 (116). The PCI and CABG guideline writing committees endorse the performance of the ISCHEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches) trial, which will provide contemporary data on the optimal management strategy (medical therapy or revascularization with CABG or

PCI) of patients with SIHD, including multivessel CAD, and moderate to severe ischemia.

2.5. PCI Versus Medical Therapy

Although contemporary interventional treatments have lowered the risk of restenosis compared with earlier techniques, meta-analyses have failed to show that the introduction of BMS confers a survival advantage over balloon angioplasty (117–119) or that the use of DES confers a survival advantage over BMS (119, 120).

No study to date has demonstrated that PCI in patients with SIHD improves survival rates (26, 53, 56, 82, 116, 119, 121–124). Neither COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) (82) nor BARI 2D (116), which treated all patients with contemporary optimal medical therapy, demonstrated any survival advantage with PCI, although these trials were not specifically powered for this endpoint. Although 1 large analysis evaluating 17 RCTs of PCI versus medical therapy (including 5 trials of subjects with acute coronary syndromes [ACS]) found a 20% reduction in death with PCI compared with medical therapy (123), 2 other large analyses did not (119, 122). An evaluation of 13 studies reporting the data from 5,442 patients with nonacute CAD showed no advantage of PCI over medical therapy for the individual endpoints of all-cause death, cardiac death or MI, or nonfatal MI (124). Evaluation of 61 trials of PCI conducted over several decades shows that despite improvements in PCI technology and pharmacotherapy, PCI has not been demonstrated to reduce the risk of death or MI in patients without recent ACS (119).

The findings from individual studies and systematic reviews of PCI versus medical therapy can be summarized as follows:

- PCI reduces the incidence of angina (82, 99, 104, 107, 108, 125).
- PCI has not been demonstrated to improve survival in stable patients (119, 121, 122).
- PCI may increase the short-term risk of MI (82, 121, 125, 126).
- PCI does not lower the long-term risk of MI (82, 116, 119, 121, 122, 126).

2.6. CABG Versus PCI

The results of 26 RCTs comparing CABG and PCI have been published: Of these, 9 compared CABG with balloon angioplasty (75, 105, 128–142), 14 compared CABG with BMS implantation (88, 143–160), and 3 compared CABG with DES implantation (14, 161, 162).

2.6.1. CABG Versus Balloon Angioplasty or BMS. A systematic review of the 22 RCTs comparing CABG with balloon angioplasty or BMS implantation concluded the following (163):

1. Survival was similar for CABG and PCI (with balloon angioplasty or BMS) at 1 year and 5 years. Survival was similar for CABG and PCI in subjects with 1-vessel CAD (including those with disease of the proximal portion of the LAD artery) or multivessel CAD.
2. Incidence of MI was similar at 5 years after randomization.
3. Procedural stroke occurred more commonly with CABG than with PCI (1.2% versus 0.6%).
4. Relief of angina was accomplished more effectively with CABG than with PCI 1 year after randomization and 5 years after randomization.
5. During the first year after randomization, repeat coronary revascularization was performed less often after CABG than after PCI (3.8% versus 26.5%). This was also demonstrated after 5 years of follow-up (9.8% versus 46.1%). This difference was more pronounced with balloon angioplasty than with BMS.

A collaborative analysis of data from 10 RCTs comparing CABG with balloon angioplasty (6 trials) or with BMS implantation (4 trials) (164) permitted subgroup analyses of the data from the 7,812 patients. No difference was noted with regard to mortality rate 5.9 years after randomization or the composite endpoint of death or MI. Repeat revascularization and angina were noted more frequently in those treated with balloon angioplasty or BMS implantation (164). The major new observation of this analysis was that CABG was associated with better outcomes in patients with diabetes mellitus and in those >65 years old. Of interest, the relative outcomes of CABG and PCI were not influenced by other patient characteristics, including the number of diseased coronary arteries.

The aforementioned meta-analysis and systematic review (163, 164) comparing CABG and balloon angioplasty or BMS implantation were limited in several ways:

1. Many trials did not report outcomes for other important patient subsets. For example, the available data are insufficient to determine if race, obesity, renal dysfunction, peripheral arterial disease, or previous coronary revascularization affected the comparative outcomes of CABG and PCI.
2. Most of the patients enrolled in these trials were male, and most had 1- or 2-vessel CAD and normal LV systolic function (EF >50%)—subjects known

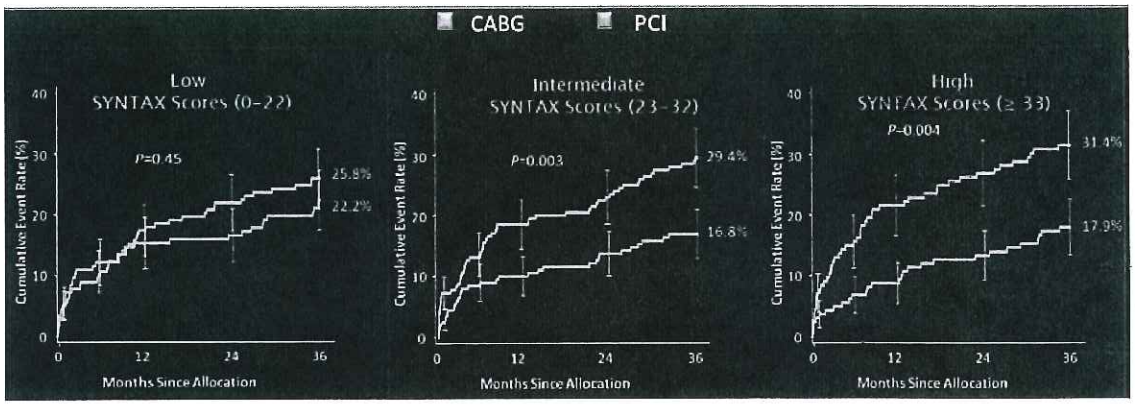

Fig. 1. Cumulative Incidence of MACE in Patients With 3-Vessel CAD Based on SYNTAX Score at 3-Year Follow-Up in the SYNTAX Trial Treated With Either CABG or PCI.

CABG indicates coronary artery bypass graft; CAD, coronary artery disease; MACE, major adverse cardiovascular event; PCI, percutaneous coronary intervention; and SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery. Adapted with permission from Kappetein (46).

to be unlikely to derive a survival benefit and less likely to experience complications after CABG (30).

3. The patients enrolled in these trials represented only a small fraction (generally <5% to 10%) of those who were screened. For example, most screened patients with 1-vessel CAD and many with 3-vessel CAD were not considered for randomization.

See Online Data Supplements 3 and 4 for additional data comparing CABG with PCI.

2.6.2. CABG Versus DES. Although the results of 9 observational studies comparing CABG and DES implantation have been published (32, 165–172), most of them had short (12 to 24 months) follow-up periods. In a meta-analysis of 24,268 patients with multivessel CAD treated with CABG or DES (173), the incidences of death and MI were similar for the 2 procedures, but the frequency with which repeat revascularization was performed was roughly 4 times higher after DES implantation. Only 1 large RCT comparing CABG and DES implantation has been published. The SYNTAX trial randomly assigned 1,800 patients (of a total of 4,337 who were screened) to receive DES or CABG (14, 46). Major adverse cardiac events (MACE), a composite of death, stroke, MI, or repeat revascularization during the 3 years after randomization, occurred in 20.2% of CABG patients and 28.0% of those undergoing DES implantation ($p<0.001$). The rates of death and stroke were similar; however, MI (3.6% for CABG, 7.1% for DES) and repeat revascularization (10.7% for CABG, 19.7% for DES) were more likely to occur with DES implantation (46).

In SYNTAX, the extent of CAD was assessed using the SYNTAX score, which is based on the location, severity, and extent of coronary stenoses, with a low score indicating less complicated anatomic CAD. In post hoc analyses, a low score was defined as ≤22; intermediate, 23 to 32; and high, ≥33. The occurrence of MACE correlated with the SYNTAX score for DES patients but not for those undergoing CABG. At 12-month follow-up, the primary endpoint was similar for CABG and DES in those with a low SYNTAX score. In contrast, MACE occurred more often after DES implantation than after CABG in those with an intermediate or high SYNTAX score (14). At 3 years of follow-up, the mortality rate was greater in subjects with 3-vessel CAD treated with PCI than in those treated with CABG (6.2% versus 2.9%). The differences in MACE between those treated with PCI or CABG increased with an increasing SYNTAX score (Figure 1) (46). F1

Although the utility of using a SYNTAX score in everyday clinical practice remains uncertain, it seems reasonable to conclude from SYNTAX and other data that outcomes of patients undergoing PCI or CABG in those with relatively uncomplicated and lesser degrees of CAD are comparable, whereas in those with complex and diffuse CAD, CABG appears to be preferable (46).

See Online Data Supplements 5 and 6 for additional data comparing CABG with DES.

2.7. Left Main CAD

2.7.1. CABG or PCI Versus Medical Therapy for Left Main CAD. CABG confers a survival benefit over medical therapy in patients with left main CAD. Subgroup analyses from RCTs performed 3 decades ago included 91 patients with left main CAD in the

Veterans Administration Cooperative Study (28). A meta-analysis of these trials demonstrated a 66% reduction in relative risk in mortality with CABG, with the benefit extending to 10 years (30). The CASS Registry (24) contained data from 1,484 patients with ≥50% diameter stenosis left main CAD initially treated surgically or nonsurgically. Median survival duration was 13.3 years in the surgical group; and 6.6 years in the medical group. The survival benefit of CABG over medical therapy appeared to extend to 53 asymptomatic patients with left main CAD in the CASS Registry (29). Other therapies that subsequently have been shown to be associated with improved long-term outcome, such as the use of aspirin, statins, and internal mammary artery grafting, were not widely used in that era.

RCTs and subgroup analyses that compare PCI with medical therapy in patients with "unprotected" left main CAD do not exist.

2.7.2. Studies Comparing PCI Versus CABG for Left Main CAD. Of all subjects undergoing coronary angiography, approximately 4% are found to have left main CAD (175), >80% of whom have significant (≥70% diameter) stenoses in other epicardial coronary arteries.

Published cohort studies have found that major clinical outcomes are similar with PCI or CABG 1 year after revascularization and that mortality rates are similar at 1, 2, and 5 years of follow-up; however, the risk of needing target-vessel revascularization is significantly higher with stenting than with CABG.

In the SYNTAX trial, 45% of screened patients with unprotected left main CAD had complex disease that prevented randomization; 89% of these underwent CABG (13, 14). In addition, 705 of the 1,800 patients who were randomized had revascularization for unprotected left main CAD. The majority of patients with left main CAD and a low SYNTAX score had isolated left main CAD or left main CAD plus 1-vessel CAD; the majority of those with an intermediate score had left main CAD plus 2-vessel CAD; and most of those with a high SYNTAX score had left main CAD plus 3-vessel CAD. At 1 year, rates of all-cause death and MACE were similar for the 2 groups (13). Repeat revascularization rates were higher in the PCI group than the CABG group (11.8% versus 6.5%), but stroke occurred more often in the CABG group (2.7% versus 0.3%). At 3 years of follow-up, the incidence of death in those undergoing left main CAD revascularization with low or intermediate SYNTAX scores (≤32) was 3.7% after PCI and 9.1% after CABG (p=0.03), whereas in those with a high SYNTAX score (≥33), the incidence of death after 3 years was 13.4% after PCI and 7.6% after CABG (p=0.10) (46). Because the primary endpoint of SYNTAX was not met (i.e., noninferiority comparison of CABG and PCI), these subgroup analyses need to be considered in that context.

In the LE MANS (Study of Unprotected Left Main Stenting Versus Bypass Surgery) trial (23), 105 patients with left main CAD were randomized to receive PCI or CABG. Although a low proportion of patients treated with PCI received DES (35%) and a low proportion of patients treated with CABG received internal mammary grafts (72%), the outcomes at 30 days and 1 year were similar between the groups. In the PRECOMBAT (Premier of Randomized Comparison of Bypass Surgery versus Angioplasty Using Sirolimus-Eluting Stent in Patients with Left Main Coronary Artery Disease) trial of 600 patients with left main disease, the composite endpoint of death, MI, or stroke at 2 years occurred in 4.4% of patients treated with PCI patients and 4.7% of patients treated with CABG, but ischemia-driven target-vessel revascularization was more often required in the patients treated with PCI (9.0% versus 4.2%) (52).

The results from these 3 RCTs suggest (but do not definitively prove) that major clinical outcomes in *selected* patients with left main CAD are similar with CABG and PCI at 1- to 2-year follow-up, but repeat revascularization rates are higher after PCI than after CABG. RCTs with extended follow-up of ≥5 years are required to provide definitive conclusions about the optimal treatment of left main CAD. In a meta-analysis of 8 cohort studies and 2 RCTs (41), death, MI, and stroke occurred with similar frequency in the PCI- and CABG-treated patients at 1, 2, and 3 years of follow-up. Target-vessel revascularization was performed more often in the PCI group at 1 year (OR: 4.36), 2 years (OR: 4.20), and 3 years (OR: 3.30).

See Online Data Supplements 7 to 12 for additional data comparing PCI with CABG for left main CAD.

2.7.3. Revascularization Considerations for Left Main CAD. Although CABG has been considered the "gold standard" for unprotected left main CAD revascularization, more recently PCI has emerged as a possible alternative mode of revascularization in carefully selected patients. Lesion location is an important determinant when considering PCI for unprotected left main CAD. Stenting of the left main ostium or trunk is more straightforward than treating distal bifurcation or trifurcation stenoses, which generally requires a greater degree of operator experience and expertise (176). In addition, PCI of bifurcation disease is associated with higher restenosis rates than when disease is confined to the ostium or trunk (39, 177). Although lesion location influences technical success and long-term outcomes after PCI, location exerts a negligible influence on the success of CABG. In subgroup analyses, patients with left main CAD and a SYNTAX score ≥33 with more

complex or extensive CAD had a higher mortality rate with PCI than with CABG (46). Physicians can estimate operative risk for all CABG candidates using a standard instrument, such as the risk calculator from the STS database. The above considerations are important factors when choosing among revascularization strategies for unprotected left main CAD and have been factored into revascularization recommendations. Use of a Heart Team approach has been recommended in cases in which the choice of revascularization is not straightforward. As discussed in Section 2.9.7, the ability of the patient to tolerate and comply with dual antiplatelet therapy (DAPT) is also an important consideration in revascularization decisions.

The 2005 PCI guideline (8) recommended routine an-giographic follow-up 2 to 6 months after stenting for unprotected left main CAD. However, because angiography has limited ability to predict stent thrombosis and the results of SYNTAX suggest good intermediate-term results for PCI in subjects with left main CAD, this recommendation was removed in the 2009 STEMI/PCI focused update (10).

Experts have recommended immediate PCI for unprotected left main CAD in the setting of STEMI (51). The impetus for such a strategy is greatest when left main CAD is the site of the culprit lesion, antegrade coronary flow is diminished (e.g., TIMI flow grade 0, 1, or 2), the patient is hemodynamically unstable, and it is believed that PCI can be performed more quickly than CABG. When possible, the interventional cardiologist and cardiac surgeon should decide together on the optimal form of revascularization for these subjects, although it is recognized that these patients are usually critically ill and therefore not amenable to a prolonged deliberation or discussion of treatment options.

2.8. Proximal LAD Artery Disease

A cohort study (53) and a meta-analysis (30) from the 1990s suggested that CABG confers a survival advantage over contemporaneous medical therapy for patients with disease in the proximal segment of the LAD artery. Cohort studies and RCTs (30, 133, 146, 148, 161, 178–181) as well as collaborative- and meta-analyses (164, 182–184) showed that PCI and CABG result in similar survival rates in these patients.

See Online Data Supplement 13 for additional data regarding proximal LAD artery revascularization.

2.9. Clinical Factors That May Influence the Choice of Revascularization

2.9.1. Diabetes Mellitus. An analysis performed in 2009 of data on 7,812 patients (1,233 with diabetes) in 10 RCTs demonstrated a worse long-term survival rate in patients with diabetes mellitus after balloon angioplasty or BMS implantation than after CABG (164). The BARI 2D trial (116) randomly assigned 2,368 patients with type 2 diabetes and CAD to undergo intensive medical therapy or prompt revascularization with PCI or CABG, according to whichever was thought to be more appropriate. By study design, those with less extensive CAD more often received PCI, whereas those with more extensive CAD were more likely to be treated with CABG.

The study was not designed to compare PCI with CABG. At 5-year follow-up, no difference in rates of survival or MACE between the medical therapy group and those treated with revascularization was noted. In the PCI stratum, no significant difference in MACE between medical therapy and revascularization was demonstrated (DES in 35%; BMS in 56%); in the CABG stratum, MACE occurred less often in the revascularization group. One-year follow-up data from the SYNTAX study demonstrated a higher rate of repeat revascularization in patients with diabetes mellitus treated with PCI than with CABG, driven by a tendency for higher repeat revascularization rates in those with higher SYNTAX scores undergoing PCI (76). In summary, in subjects requiring revascularization for multivessel CAD, current evidence supports diabetes mellitus as an important factor when deciding on a revascularization strategy, particularly when complex or extensive CAD is present (Figure 2). F2

See Online Data Supplements 14 and 15 for additional data regarding diabetes mellitus.

2.9.2. Chronic Kidney Disease. Cardiovascular morbidity and mortality rates are markedly increased in patients with chronic kidney disease (CKD) when compared with age-matched controls without CKD. The mortality rate for patients on hemodialysis is >20% per year, and approximately 50% of deaths among these patients are due to a cardiovascular cause (187, 188).

To date, randomized comparisons of coronary revascularization (with CABG or PCI) and medical therapy in patients with CKD have not been reported. Some, but not all, observational studies or subgroup analyses have demonstrated an improved survival rate with revascularization compared with medical therapy in patients with CKD and multivessel CAD (189–191), despite the fact that the incidence of periprocedural complications (e.g., death, MI, stroke, infection, renal failure) is increased in patients with CKD compared with those without renal dysfunction. Some studies have shown that CABG is associated with a greater survival benefit than PCI among patients with severe renal dysfunction (190–196).

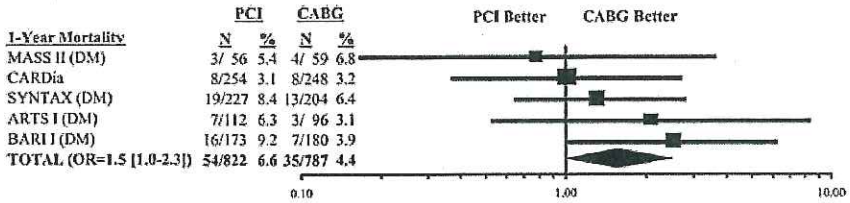

Fig. 2. 1-Year Mortality After Revascularization for Multivessel Disease and Diabetes Mellitus.

An OR of >1 suggests an advantage of CABG over PCI. ARTS I indicates Arterial Revascularization Therapy Study I (185); BARI I, Bypass Angioplasty Revascularization Investigation I (74); CABG, coronary artery bypass graft; CAD, coronary artery disease; CARDia, Coronary Artery Revascularization in Diabetes (186); CI, confidence interval; MASS II, Medicine, Angioplasty, or Surgery Study II (78); OR, odds ratio; PCI, percutaneous coronary intervention; SYNTAX, Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery; and W, weighted (76).

2.9.3. Completeness of Revascularization. Most patients undergoing CABG receive complete or nearly complete revascularization, which seems to influence long-term prognosis positively (197). In contrast, complete revascularization is accomplished less often in subjects receiving PCI (e.g., in <70% of patients), but the extent to which the absence of complete initial revascularization influences outcome is less clear. Rates of late survival and survival free of MI appears to be similar in patients with and without complete revascularization after PCI. Nevertheless, the need for subsequent CABG is usually higher in those whose initial revascularization procedure was incomplete (compared with those with complete revascularization) after PCI (198–200).

2.9.4. LV Systolic Dysfunction. Several older studies and a meta-analysis of the data from these studies reported that patients with LV systolic dysfunction (predominantly mild to moderate in severity) had better survival with CABG than with medical therapy alone (30, 64–68). For patients with more severe LV systolic dysfunction, however, the evidence that CABG results in better survival compared with medical therapy is lacking. In the STICH (Surgical Treatment for Ischemic Heart Failure) trial of subjects with LVEF <35% with or without viability testing, CABG and GDMT resulted in similar rates of survival (death from any cause, the study's primary outcome) after 5 years of follow-up. For a number of secondary outcomes at this time point, including 1) death from any cause or hospitalization for heart failure, 2) death from any cause or hospitalization for cardiovascular causes, 3) death from any cause or hospitalization for any cause, or 4) death from any cause or revascularization with PCI or CABG, CABG was superior to GDMT. Although the primary outcome (death from any cause) was similar in the 2 treatment groups after an average of 5 years of follow-up, the data suggest the possibility that outcomes would differ if the follow-up were longer in duration; as a result, the study is being continued to provide follow-up for up to 10 years (83, 84).

Only very limited data comparing PCI with medical therapy in patients with LV systolic dysfunction are available (68). In several ways, these data are suboptimal, in that many studies compared CABG with balloon angioplasty, many were retrospective, and many were based on cohort or registry data. Some of the studies demonstrated a similar survival rate in patients having CABG and PCI (71, 164, 201–203), whereas others showed that those undergoing CABG had better outcomes (32). The data that exist at present on revascularization in patients with CAD and LV systolic dysfunction are more robust for CABG than for PCI, although data from contemporary RCTs in this patient population are lacking. Therefore, the choice of revascularization in patients with CAD and LV systolic dysfunction is best based on clinical variables (e.g., coronary anatomy, presence of diabetes mellitus, presence of CKD), magnitude of LV systolic dysfunction, patient preferences, clinical judgment, and consultation between the interventional cardiologist and the cardiac surgeon.

2.9.5. Previous CABG. In patients with recurrent angina after CABG, repeat revascularization is most likely to improve survival in subjects at highest risk, such as those with obstruction of the proximal LAD artery and extensive anterior ischemia (85–93). Patients with ischemia in other locations and those with a patent LIMA to the LAD artery are unlikely to experience a survival benefit from repeat revascularization (92).

Cohort studies comparing PCI and CABG among post-CABG patients report similar rates of mid- and long-term survival after the 2 procedures (85, 88–91, 93, 204). In the patient with previous CABG who is referred for revascularization for medically refractory ischemia, factors that may support the choice of repeat CABG include vessels unsuitable for PCI, number of diseased bypass grafts, availability of the internal mammary artery for grafting chronically occluded coronary arteries, and good distal targets for bypass graft placement. Factors favoring PCI over CABG include limited areas of ischemia causing symptoms, suitable

PCI targets, a patent graft to the LAD artery, poor CABG targets, and comorbid conditions.

2.9.6. Unstable Angina/Non-ST-Elevation Myocardial Infarction. The main difference between management of the patient with SIHD and the patient with UA/NSTEMI is that the impetus for revascularization is stronger in the setting of UA/NSTEMI, because myocardial ischemia occurring as part of an ACS is potentially life threatening, and associated anginal symptoms are more likely to be reduced with a revascularization procedure than with GDMT (205–207). Thus, the indications for revascularization are strengthened by the acuity of presentation, the extent of ischemia, and the ability to achieve full revascularization. The choice of revascularization method is generally dictated by the same considerations used to decide on PCI or CABG for patients with SIHD.

2.9.7. DAPT Compliance and Stent Thrombosis: Recommendation

CLASS III: HARM

1. PCI with coronary stenting (BMS or DES) should not be performed if the patient is not likely to be able to tolerate and comply with DAPT for the appropriate duration of treatment based on the type of stent implanted (208–211). *(Level of Evidence: B)*

The risk of stent thrombosis is increased dramatically in patients who prematurely discontinue DAPT, and stent thrombosis is associated with a mortality rate of 20% to 45% (208). Because the risk of stent thrombosis with BMS is greatest in the first 14 to 30 days, this is the generally recommended minimum duration of DAPT therapy for these individuals. Consensus in clinical practice is to treat DES patients for at least 12 months with DAPT to avoid late (after 30 days) stent thrombosis (208, 212). Therefore, the ability of the patient to tolerate and comply with at least 30 days of DAPT with BMS treatment and at least 12 months of DAPT with DES treatment is an important consideration in deciding whether to use PCI to treat patients with CAD.

2.10. TMR as an Adjunct to CABG

TMR has been used on occasion in patients with severe angina refractory to GDMT in whom complete revascularization cannot be achieved with PCI and/or CABG. Although the mechanism by which TMR might be efficacious in these patients is unknown (213, 214), several RCTs of TMR as sole therapy demonstrated a reduction in anginal symptoms compared with intensive medical therapy alone (109–111, 215–217). A single randomized multicenter comparison of TMR (with a holmium: YAG laser) plus CABG and CABG alone in patients in whom some myocardial segments were perfused by arteries considered not amenable to grafting (112) showed a significant reduction in perioperative mortality rate (1.5% versus 7.6%, respectively), and the survival benefit of the TMR–CABG combination was present after 1 year of follow-up (112). At the same time, a large retrospective analysis of data from the STS National Cardiac Database as well as a study of 169 patients from the Washington Hospital Center who underwent combined TMR–CABG, showed no difference in adjusted mortality rate compared with CABG alone (113, 218). In short, a TMR–CABG combination does not appear to improve survival compared with CABG alone. In selected patients, however, such a combination may be superior to CABG alone in relieving angina.

2.11. Hybrid Coronary Revascularization: Recommendations

CLASS IIa

1. Hybrid coronary revascularization (defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries) is reasonable in patients with 1 or more of the following (219–225) *(Level of Evidence: B):*
   a. Limitations to traditional CABG, such as heavily calcified proximal aorta or poor target vessels for CABG (but amenable to PCI);
   b. Lack of suitable graft conduits;
   c. Unfavorable LAD artery for PCI (i.e., excessive vessel tortuosity or CTO).

CLASS IIb

Hybrid coronary revascularization (defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries) may be reasonable as an alternative to multivessel PCI or CABG in an attempt to improve the overall risk-benefit ratio of the procedures. *(Level of Evidence: C)*

Hybrid coronary revascularization, defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries (226), is intended to combine the advantages of CABG (i.e., durability of the LIMA graft) and PCI (227). Patients with multivessel CAD (e.g., LAD and ≥1 non-LAD stenoses) and an indication for revascularization are potentially eligible for this approach. Hybrid revascularization is ideal in patients in whom technical or anatomic limitations to CABG or PCI alone may be present and for whom minimizing the invasiveness (and therefore the risk of morbidity and mortality) of surgical intervention is preferred (221) (e.g., patients with

severe preexisting comorbidities, recent MI, a lack of suitable graft conduits, a heavily calcified ascending aorta, or a non-LAD coronary artery unsuitable for bypass but amenable to PCI, and situations in which PCI of the LAD artery is not feasible because of excessive tortuosity or CTO).

Hybrid coronary revascularization may be performed in a hybrid suite in one operative setting or as a staged procedure (i.e., PCI and CABG performed in 2 different operative suites, separated by hours to 2 days, but typically during the same hospital stay). Because most hospitals lack a hybrid operating room, staged procedures are usually performed. With the staged procedure, CABG before PCI is preferred, because this approach allows the interventional cardiologist to 1) verify the patency of the LIMA-to-LAD artery graft before attempting PCI of other vessels and 2) minimize the risk of perioperative bleeding that would occur if CABG were performed after PCI (i.e., while the patient is receiving DAPT). Because minimally invasive CABG may be associated with lower graft patency rates compared with CABG performed through a midline sternotomy, it seems prudent to angiographically image all grafts performed through a minimally invasive approach to confirm graft patency (221).

To date, no RCTs involving hybrid coronary revascularization have been published. Over the past 10 years, several small, retrospective series of hybrid revascularization using minimally invasive CABG and PCI have reported low mortality rates (0 to 2%) and event-free survival rates of83% to 92% at 6 to 12 months of follow-up. The few series that have compared the outcomes of hybrid coronary revascularization with standard CABG report similar outcomes at 30 days and 6 months (219–225).

3. PCI OUTCOMES

3.1. Definitions of PCI Success

The success of a PCI procedure is best defined by 3 interrelated components: angiographic findings, procedural events, and clinical outcomes.

3.1.1. Angiographic Success. A successful PCI produces sufficient enlargement of the lumen at the target site to improve coronary artery blood flow. A successful balloon angioplasty is defined as the reduction of a minimum stenosis diameter to <50% with a final TIMI flow grade 3 (visually assessed by angiography) without side branch loss, flow-limiting dissection, or angiographic thrombus (7). For coronary stents, a minimum stenosis diameter of <20% (as visually assessed by angiography) has previously been the clinical benchmark of an optimal angiographic result. Given improvements in technology and techniques, as well as recognition of the importance of an adequately deployed stent to decrease the risks of stent restenosis and thrombosis (12, 228, 229), the writing committee concluded that a minimum diameter stenosis of < 10% (with an optimal goal of as close to 0% as possible) should be the new benchmark for lesions treated with coronary stenting. As with balloon angioplasty, there should be final TIMI flow grade 3, without occlusion of a significant side branch, flow-limiting dissection, distal embolization, or angiographic thrombus. Problems with determining angiographic success include disparities between the visual assessment and computer-aided quantitative stenosis measurement and self-reporting of success in clinical reports or databases.

3.1.2. Procedural Success. A successful PCI should achieve angiographic success without associated in-hospital major clinical complications (e.g., death, MI, stroke, emergency CABG) (7, 8). Issues regarding the diagnosis and prognostic implications of procedure-related MI are discussed in Sections 3.3 and 5.10.

3.1.3. Clinical Success. In the short term, a clinically successful PCI requires both anatomic and procedural success along with relief of signs and/or symptoms of myocardial ischemia. Long-term clinical success requires that the short-term clinical success remain durable and that relief of signs and symptoms of myocardial ischemia persist >9 months after the procedure. Restenosis is the principal cause of lack of long-term clinical success after a short-term clinical success has been achieved. Restenosis is not a complication; it is the expected biological response to vascular injury. The frequency of clinically important restenosis may be judged by the frequency with which subsequent revascularization procedures are performed on target arteries after the index procedure.

3.2. Predictors of Clinical Outcome After PCI

Factors associated with increased PCI complication rates include advanced age, diabetes, CKD, ACS, congestive heart failure, and multivessel CAD (8, 230–232). Several models have been developed and refined over the past 2 decades to predict mortality with PCI (230, 233–236). At present, perhaps the best accepted system is from the ACC National Cardiovascular Data Registry (NCDR) CathPCI Risk Score system, which uses clinical variables and PCI setting to predict inpatient mortality (Appendix 4A)(236). In general, these models perform very well (C statistic: approximately 0.90), although predictive capability decreases in high-risk patients.

Models have also been developed to predict procedural success. Presently, the modified ACC/AHA score

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

(230) and the SCAI score (Appendix 4B)(237) are both in use, with the latter slightly outperforming the former. Discrimination as measured by the C statistic is generally good to very good (0.70 to 0.82), depending on the outcome variable and patient population.

The angiographic SYNTAX score (238) has been developed to predict long-term risk of MACE after multivessel intervention. The SYNTAX score and its potential utility in helping guide revascularization strategies are discussed in Section 2. Composite models including angiographic and clinical variables have been developed but generally require validation in larger cohorts of patients.

3.3. PCI Complications

In an analysis of the NCDR CathPCI database of patients undergoing PCI between 2004 and 2007, the overall in-hospital mortality rate was 1.27%, ranging from 0.65% in elective PCI to 4.81% in STEMI (236). Factors associated with an increased risk of PCI-related death include advanced age, comorbidities (e.g., diabetes, CKD, congestive heart failure), multivessel CAD, high-risk lesions, and the setting of PCI (e.g., STEMI, urgent or emergency procedure, cardiogenic shock) (56, 230–232, 236).

Causes of procedural and periprocedural MI include acute artery closure, embolization and no-reflow, side branch occlusion, and acute stent thrombosis. The incidence of procedure-related MI depends to a great degree on the definition of MI used, the patient population studied, and whether or not cardiac biomarkers are routinely assessed after PCI. The definition and clinical significance of PCI-related MI have been controversial. Criteria for defining a PCI-related MI have evolved over time (8, 239, 240). The 2007 universal definition of MI (240) states that after PCI, elevations of cardiac biomarkers above the 99th percentile upper reference limit indicate periprocedural myocardial necrosis. Increases of biomarkers >3 times the 99th percentile upper reference limit were designated as defining PCI-related MI (240). According to this definition, ≥15% of patients undergoing PCI would be defined as having periprocedural MI (241, 242). Issues in procedure-related MI are discussed in Section 5.10.

The need for emergency CABG has dramatically decreased with advances in PCI technology, particularly coronary stents (243, 244). Recently the NCDR reported the rate of emergency CABG at 0.4% (244). Procedure-related indications for CABG in 1 large series included coronary dissection (27%), acute artery closure (16%), perforation (8%), and failure to cross the lesion (8%) (245). The strongest predictors of the need for emergency CABG in several analyses are cardiogenic shock (OR: 11.4), acute MI or emergency PCI (OR: 3.2 to 3.8), multivessel disease (OR: 2.3 to 2.4), and type C lesion (OR: 2.6) (243, 245). In-hospital mortality for emergency CABG ranges from 7.8% to 14% (243, 245, 246).

In a contemporary analysis from the NCDR, the incidence of PCI-related stroke was 0.22% (247). In-hospital mortality in patients with PCI-related stroke is 25% to 30% (247, 248). Factors associated with an increased risk of stroke include fibrinolytic therapy administered before PCI (OR: 4.7), known cerebrovascular disease (OR: 2.20), STEMI as the indication for PCI (OR: 3.2), use of an intra-aortic balloon pump (IABP) (OR: 2.6), older age (OR: 1.17 per 5-year increase), and female sex (247–249). Initial imaging after a stroke in 1 small series revealed hemorrhagic etiology in 18%, ischemic etiology in 58%, and no clear etiology in 24% (248). One potential algorithm for the treatment of catheterization-related stroke has been recently proposed (250). This document includes no specific recommendations for the management of PCI-related stroke but refers the reader to the AHA/American Stroke Association guidelines for the management of adults with stroke (251).

Vascular complications from PCI are primarily related to vascular access. Important femoral vascular complications include access site hematoma, retroperitoneal hematoma, pseudoaneurysm, arteriovenous fistula, and arterial dissection and/or occlusion (252). The incidence of these vascular complications in various reports generally ranges from 2% to 6% and has decreased with time (249, 253–257). Factors associated with an increased risk of vascular complication include age ≥70 years, body surface area <1.6 m^2, emergency procedures, peripheral artery disease, periprocedural use of glycoprotein (GP) IIb/IIIa inhibitors, and female sex (if not corrected for body surface area) (249, 253, 254, 257, 258). Ultrasound guidance has been used for femoral artery access to potentially decrease complications (259). As discussed in Section 5.11, vascular closure devices have not been clearly demonstrated to decrease vascular complication rates. Radial site access decreases the rate of access-related bleeding and complications compared with femoral access (255, 260). Loss of the radial pulse has been reported in ≤5% of radial procedures (261). Infrequent to rare complications occurring with the radial artery approach include compartment syndrome, pseudoaneurysm (<0.01%), and sterile abscess (occurring with previous-generation hydrophilic sheaths) (262). Radial artery spasm may occur and treatment at times may be challenging. Local hematomas may occur from small-branch vessel hydrophilic wire perforation or inexperience with wristband use.

The risk of coronary perforation is approximately 0.2%, most commonly by wire perforation during PCI for CTO or by ablative or oversized devices during PCI of heavily diseased or tortuous coronary arteries (263). The risk of tamponade and management of the perforation varies with the type of perforation (264).

Periprocedural bleeding is now recognized to be associated with subsequent mortality (265, 266), and the avoidance of bleeding complications has become an important consideration in performing PCI. The risk of bleeding is associated with patient factors (e.g., advanced age, low body mass index, CKD, baseline anemia), as well as the degree of platelet and thrombin inhibition, vascular access site, and sheath size (267–269). Issues of periprocedural bleeding are discussed in Section 4.7.

The incidence of contrast-induced acute kidney injury (AKI) or "contrast nephropathy" in published reports depends on the definition of contrast nephropathy used and the frequency of risk factors for contrast-induced AKI in the patient population studied. Important risk factors for contrast-induced AKI include advanced age, CKD, congestive heart failure, diabetes, and the volume of contrast administered. Contrast-induced AKI and strategies to prevent it are discussed in Section 4.4.

4. PREPROCEDURAL CONSIDERATIONS

T4 Table 4 contains recommendations for preprocedural considerations and interventions in patients undergoing PCI.

4.1. Cardiac Catheterization Laboratory Requirements

4.1.1. Equipment. Defibrillators are considered by The Joint Commission to be life-support equipment requiring routine assessment and completion of appropriate logs. Many hospitals require periodic inspection of consoles for ancillary devices used in coronary intervention (e.g., Doppler wires, pressure-tipped sensor wires, and IVUS catheters). Point-of-care testing devices (e.g., activated clotting time and arterial blood gas machines) require routine calibration. Duration of storage of digital cine images is often mandated by law. Operating parameters for x-ray imaging equipment are adjusted at installation and periodically assessed by a qualified physicist in cooperation with the equipment manufacturer. Familiarity with radiation dose-reducing features of catheterization laboratory equipment and assistance from a qualified physicist are important for radiation dose minimization and image optimization.

4.1.2. Staffing. An interventional cardiologist must be present in the laboratory for the duration of each procedure and is responsible for procedure outcome. Nursing and technical personnel are also required to be present in the catheterization laboratory, with specific staffing dependent on state requirements and laboratory caseload and mix. Catheterization laboratory technical staff may include nurse practitioners, registered nurses, licensed vocational or practical nurses, physician assistants, nursing assistants, radiology technicians, or catheterization laboratory technicians. All catheterization laboratory staff are usually certified in basic life support, advanced cardiovascular life support, and, where appropriate, pediatric advanced life support. Catheterization laboratory personnel have a nursing degree/certification or invasive cardiovascular credentials such as registered cardiovascular invasive specialist or American Society of Radiation technologists (305).

4.1.3. 'Time-Out' Procedures. In 2003, The Joint Commission mandated a universal protocol requiring proper preoperative identification of the patient by the members of the catheterization laboratory team, marking of the operative site, and a final time-out just before the procedure (306). Although initially intended to prevent wrong-site surgery, this has been expanded to include all invasive procedures despite limited scientific evidence of its effectiveness (307). The intent of the time-out is for all members of the team to improve patient care by collectively discussing the case. The content of a time-out includes confirmation of the correct patient, correct side and site, agreement on the procedure to be performed, correct patient position, and availability of needed equipment, supplies, and implants. The timeout may be checklist driven or conversational, depending on laboratory preferences (308). The writing committee strongly endorses the practice of conducting a time-out before all PCI procedures.

4.2. Ethical Aspects

The 3 principles of medical ethics are beneficence, autonomy, and justice. Beneficence involves the physician's duty to act in the best interests of the patient and avoid maleficence, or harm *(primum non nocere)*. Autonomy describes the physician's duty to help the patient maintain control over his or her medical treatments. Justice describes the physician's duty to treat the individual patient responsibly with due consideration of other patients and stakeholders in the healthcare system. Ethical considerations specific to PCI have been previously discussed (309) and are highlighted below:

- Place the patient's best interest first and foremost when making clinical decisions (beneficence).
- Ensure that patients actively participate in decisions affecting their care (autonomy).

TABLE 4. Summary of Recommendations for Preprocedural Considerations and Interventions in Patients Undergoing PCI

Recommendations	COR	LOE	References
Contrast-Induced AKI			
Patients should be assessed for risk of contrast-induced AKI before PCI.	I	C	(270,271)
Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration.	I	B	(272–275)
In patients with CKD (creatinine clearance <60 mL/min), the volume of contrast media should be minimized.	I	B	(276–278)
Administration of N-acetyl-L-cysteine is not useful for the prevention of contrast-induced AKI.	III: No Benefit	A	(279–283)
Anaphylactoid reactions			
Patients with prior evidence of an anaphylactoid reaction to contrast media should receive appropriate prophylaxis before repeat contrast administration.	I	B	(252,284–286)
In patients with a prior history of allergic reactions to shellfish or seafood, anaphylactoid prophylaxis for contrast reaction is not beneficial.	III: No Benefit	C	(287–289)
Statins			
Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI.	IIa	A: Statin naive	(290–296)
		B: Chronic statin therapy	(297)
Bleeding risk			
All patients should be evaluated for risk of bleeding before PCI.	I	C	N/A
CKD			
In patients undergoing PCI, the glomerular filtration rate should be estimated and the dosage of renally cleared medications should be adjusted.	I	B	(298–300)
Aspirin			
Patients already on daily aspirin therapy should take 81 mg to 325 mg before PCI.	I	B	(301–304)
Patients not on aspirin therapy should be given nonenteric aspirin 325 mg before PCI.	I	B	(301,303,304)

AKI indicates acute kidney injury; CKD, chronic kidney disease; COR, class of recommendation; LOE, level of evidence; MI, myocardial infarction; N/A, not applicable; and PCI, percutaneous coronary intervention.

- Consider how decisions regarding one patient may also affect other patients and providers (justice).
- Plan and perform procedures and provide care with the intention of improving the patient's quality of life and/or decreasing the risk of mortality, independent of reimbursement considerations and without inappropriate bias or influence from industry, administrators, referring physicians, or other sources.
- Before performing procedures, obtain informed consent after giving an explanation regarding the details of the procedure and the risks and benefits of both the procedure and alternatives to the procedure.
- Plan and perform procedures according to standards of care and recommended guidelines, and deviate from them when appropriate or necessary in the care of individual patients.
- Seek advice, assistance, or consultation from colleagues when such consultation would benefit the patient.

4.2.1. Informed Consent. Obtaining informed consent for procedures is a legal and ethical necessity. Ideally, informed consent is obtained long enough before the procedure that the patient can fully consider informed consent issues and discuss them with family or other providers, avoiding any sense of coercion. Ad hoc PCI, or PCI immediately following diagnostic procedures, presents special problems. When informed consent for PCI is obtained before diagnostic catheterization is performed, it is impossible to predict the levels of risk and benefit from an ad hoc PCI (310, 311). If diagnostic catheterization reveals anatomy that poses a particularly high risk or for which the superiority of PCI compared with other strategies is unclear, the precatheterization informed consent discussion may be inadequate. In such cases, deferral of PCI until additional informed consent discussions and/or consultations occur may be appropriate, even though it inconveniences the patient and the healthcare system. It is the responsibility of the interventionalist to act in the patient's best interest in these circumstances.

Informed consent before emergency procedures is particularly difficult (312–314). The patient presenting with STEMI is usually in distress and often sedated, making true informed consent impossible. Rapid triage, transport, and treatment of STEMI patients create a pressured atmosphere that by necessity limits a prolonged and detailed informed consent process. Nevertheless, the interventionist must attempt to provide information about the risks and benefits of different strategies to the patient and family and balance the benefit of thorough discussion with the benefits of rapid intervention.

4.2.2. Potential Conflicts of Interest. Decisions about the performance and timing of PCI may pose additional ethical dilemmas. When considering whether to perform multivessel PCI in 1 stage versus 2 stages, safety and convenience for the patient must guide the decision, regardless of payment policies that maximize reimbursement when PCI is staged (311). A separate issue is self-referral, through which diagnostic catheterization often leads seamlessly to PCI by the same operator (315). The interventionist has an ethical obligation to the patient to consider all treatment options, consult with additional specialists (e.g., cardiac surgeons) when their input would be helpful to the patient, avoid unnecessary interventional procedures, and allow the patient to consult family members and other physicians (311).

4.3. Radiation Safety: Recommendation

CLASS I

1. Cardiac catheterization laboratories should routinely record relevant available patient procedural radiation dose data (e.g., total air kerma at the international reference point [$K_{a,r}$], air kerma air product [P_{KA}], fluoroscopy time, number of cine images), and should define thresholds with corresponding follow-up protocols for patients who receive a high procedural radiation dose. *(Level of Evidence: C)*

The issue of radiation exposure during imaging procedures has received increased attention, and the writing committee believes that radiation safety should be addressed in this guideline. Current standards for cardiac catheterization laboratories include the following:

- Specific procedures and policies are in place to minimize patient (and operator) risk.
- A radiation safety officer coordinates all radiation safety issues and works conjointly with the medical or health physicist.
- Patient radiation exposure is reduced to as low a level as reasonably can be achieved.
- Patients at increased risk for high procedural radiation exposure are identified.
- Informed consent includes radiation safety information, particularly for the high-risk patient.

A basic primer on the physics of x-ray imaging, essential to the safe practice of radiation dose management, has been published in an ACCF/AHA/Heart Rhythm Society/SCAI clinical competence statement (316). Appendix 4C summarizes strategies to minimize patient and operator radiation exposure. Adverse radiation effects are now well recognized as infrequent but potentially serious complications of prolonged interventional procedures (317). Fluoroscopic time does not include cine acquisition imaging and is therefore not an accurate measure of patient radiation dose. Total air kerma at the interventional reference point ($K_{a,r}$, in G_y) and air kerma area product (P_{KA}, in $Gycm^2$) are required to be reported on interventional x-ray systems since 2006.These are useful in the assessment of potential tissue adverse effects or long-term radiation sequelae, respectively, and it is reasonable to include them in the catheterization record at the conclusion of each procedure. Appendix 4D summarizes considerations for patient follow-up based on radiation dose during the procedure (317).

4.4. Contrast-Induced AKI: Recommendations

CLASS I

1. Patients should be assessed for risk of contrast-induced AKI before PCI (270, 271). *(Level of Evidence: C)*
2. Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration (272–275). *(Level of Evidence: B)*
3. In patients with CKD (creatinine clearance <60 mL/min), the volume of contrast media should be minimized (276–278). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. Administration of N-acetyl-L-cysteine is not useful for the prevention of contrast-induced AKI (279–283). *(Level of Evidence: A)*

See Online Data Supplements 16 to 18 for additional data regarding contrast-induced AKI.

Contrast-induced AKI or "contrast nephropathy" is one of the leading causes of hospital-acquired AKI. Major risk factors for contrast-induced AKI include advanced age, CKD, congestive heart failure, diabetes, and the volume of contrast administered. A risk-scoring system is available to predict the risk of contrast nephropathy using these risk factors and additional variables (270). Thus far, the only strategies clearly shown to reduce the risk of contrast-induced AKI are hydration and minimizing the amount of contrast media. Other than saline hydration, measures that were believed to reduce the risk of contrast-induced AKI have been found to be neutral, to have deleterious effects, or to be characterized by heterogeneous and conflicting data.

Studies of hydration to reduce the risk of contrast-induced AKI suggest that isotonic saline is preferable to half isotonic saline, intravenous (IV) hydration is preferable to oral hydration, hydration for hours before and after exposure to contrast media is preferable to a

bolus administration of saline immediately before or during contrast media exposure, and administration of isotonic saline alone is preferable to administration of isotonic saline plus mannitol or furosemide (272–275, 320). On the basis of these studies, a reasonable hydration regimen would be isotonic crystalloid (1.0 to 1.5 mL/kg per hour) for 3 to 12 hours before the procedure and continuing for 6 to 24 hours after the procedure (272–275, 284, 320, 321).

Prior studies of N-acetyl-L-cysteine and sodium bicarbonate have produced conflicting results. Some, often small, earlier studies suggested benefit, but many other more contemporary studies and meta-analyses found no clear evidence of benefit, and there are potential issues of publication bias and poor methodology issues in several analyses (279–282, 322–332). The recently completed largest randomized study on N-acetyl-L-cysteine and contrast nephropathy in patients undergoing angiographic procedures, ACT (Acetylcysteine for Contrast-Induced Nephropathy Trial), demonstrated no benefit in primary or secondary endpoints. An updated meta-analysis using only high-quality trials similarly demonstrated no benefit (283). Taken as a whole, these studies do not support any recommendation for the use of N-acetyl-L-cysteine, they do, however, provide sufficient data to conclude that N-acetyl-L-cysteine does not prevent contrast-induced AKI in patients undergoing angiographic procedures.

The correlation between the volume of contrast media and the risk of contrast-induced AKI has been documented in several studies (276, 277). Thus, minimization of contrast media volume is important to prevent contrast-induced AKI in patients undergoing angiography. The volume of contrast already administered during diagnostic catheterization is an important factor when considering possible "ad hoc" PCI.

Comparative studies of different contrast media (e.g., low-osmolar versus iso-osmolar, one agent versus another agent) have produced variable and sometimes contradictory results (334–339). Thus, current data are insufficient to justify specific recommendations about low- and isoosmolar contrast media. This issue is discussed in detail in the 2011 UA/NSTEMI focused update (340). For a further discussion of contrast media and PCI, the reader is referred to a position statement by the SCAI (284).

4.5. Anaphylactoid Reactions: Recommendations

CLASS I

1. Patients with prior evidence of an anaphylactoid reaction to contrast media should receive appropriate steroid and antihistamine prophylaxis before repeat contrast administration (252, 284–286). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. In patients with a prior history of allergic reactions to shellfish or seafood, anaphylactoid prophylaxis for contrast reaction is not beneficial (287–289). *(Level of Evidence: C)*

The incidence of anaphylactoid reactions to contrast media is $\leq$1%, and the incidence of severe reactions may be as low as 0.04% (284). Limited data suggest that in patients with a history of prior anaphylactoid reaction, the recurrence rate without prophylaxis is in the range of 16% to 44% (341). Adequate pretreatment of patients with prior anaphylactoid reactions reduces the recurrence rate to close to zero (284–286). A regimen of 50 mg of prednisone administered 13 hours, 7 hours, and 1 hour before the procedure (as well as 50 mg of diphenhydramine 1 hour before the procedure) has been shown to reduce the risk of recurrent anaphylactoid reaction (286). In practice, a regimen of 60 mg of prednisone the night before and morning of the procedure (as well as 50 mg of diphenhydramine 1 hour before the procedure) is often used (252). There are minimal data on the "pretreatment" of patients undergoing emergency PCI (342). One group has suggested IV steroids (e.g., 80 mg to 125 mg of methylprednisolone, 100 mg of hydrocortisone sodium succinate), as well as oral or IV diphenhydramine and possible IV cimetidine (284). For a more detailed discussion of issues related to contrast-induced anaphylactoid reactions, the reader is referred to several dedicated discussions on contrast agents (284, 341).

There are no data to suggest that those patients with seafood or shellfish allergies are at risk for an anaphylactoid reaction from exposure to contrast media. Iodine does not mediate seafood, shellfish, or contrast media reactions. The common misconception that seafood allergies and contrast reactions are cross-reactions to iodine probably arose from a survey published in 1975 in which 15% of patients with a history of contrast reaction reported a personal history of shellfish allergy, but nearly identical proportions of patients reported allergies to other foods, such as milk and egg, in the same survey (287). Pretreatment of patients with steroids based only on a history of seafood or shellfish allergy has a small but non-zero risk of adverse effect (e.g., hyperglycemia in a patient with diabetes) without any demonstrated benefit (288, 289).

4.6. Statin Treatment: Recommendation

CLASS IIa

1. Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI. *(Level of Evidence: A for statin-naive patients* [290–296]; *Level of Evidence: B for those on chronic statin therapy* [297])

See Online Data Supplement 19 for additional data regarding preprocedural statin treatment.

Statins have long-term benefits in patients with CAD (343, 344) and ACS (345, 346). The benefits of statins in ACS begin early, before substantial lipid lowering has occurred (345, 347), suggesting pleiotropic effects of statins. These might include anti-inflammatory effects, improvement of endothelial function, decrease of oxidative stress, or inhibition of thrombogenic responses (348). Statins were beneficial when pretreatment was started from 7 days to just before PCI (290–297).

4.7. Bleeding Risk: Recommendation

CLASS I

1. All patients should be evaluated for risk of bleeding before PCI. *(Level of Evidence: C)*

Periprocedural bleeding is now recognized as a major risk factor for subsequent mortality (265, 266). Bleeding may lead to mortality directly (because of the bleeding event) or through ischemic complications that occur when antiplatelet or anticoagulant agents are withdrawn in response to the bleeding. Bleeding may also be a marker of comorbidities associated with worse prognosis (e.g., occult cancer). The risk of bleeding is associated with a number of patient factors (e.g., advanced age, low body mass index, CKD, baseline anemia), as well as the degree of platelet and thrombin inhibition, vascular access site, and sheath size (267–269). The overall approach to PCI should be individualized to minimize both ischemic and bleeding risks.

Measures to minimize the risks of bleeding complications are discussed in several sections of this guideline. These include use of anticoagulation regimens associated with a lower risk of bleeding, weight-based dosing of heparin and other agents, use of activated clotting times to guide unfractionated heparin (UFH) dosing, avoidance of excess anticoagulation (349), dosing adjustments in patients with CKD (e.g., eptifibatide, tirofiban, bivalirudin) (350), use of radial artery access site (255), and avoidance of femoral vein cannulation when possible. Vascular closure devices have not been clearly demonstrated to decrease bleeding complications and are discussed in detail in Section 5.11.

4.8. PCI in Hospitals Without On-Site Surgical Backup: Recommendations

CLASS IIa

1. Primary PCI is reasonable in hospitals without on-site cardiac surgery, provided that appropriate planning for program development has been accomplished (351, 352). *(Level of Evidence: B)*

CLASS IIb

1. Elective PCI might be considered in hospitals without on-site cardiac surgery, provided that appropriate planning for program development has been accomplished and rigorous clinical and angiographic criteria are used for proper patient selection (352–354). *(Level of Evidence: B)*

CLASS III: HARM

1. Primary or elective PCI should not be performed in hospitals without on-site cardiac surgery capabilities without a proven plan for rapid transport to a cardiac surgery operating room in a nearby hospital or without appropriate hemodynamic support capability for transfer. *(Level of Evidence: C)*

See Online Data Supplement 20 for additional data regarding hospitals without on-site surgical backup.

Primary and elective PCI can be performed at hospitals without on-site cardiac surgical backup with a high success rate, low in-hospital mortality rate, and low rate for emergency CABG (351, 353, 354). The best outcomes for patients with STEMI are achieved at hospitals with 24/7 access to primary PCI (355). Criteria for the performance of PCI without on-site surgical backup have been proposed in an SCAI expert consensus document (352). Consideration of elective PCI without on-site cardiac surgical backup is thought to be appropriate only when performed by experienced operators with complication rates and outcomes equivalent or superior to national benchmarks. Accurate assessment of complication rates and patient outcomes via a regional or national data registry, so that outcomes can be compared with established benchmarks, is an important quality control component of any PCI program. Desires for personal or institutional financial gain, prestige, market share, or other similar motives are not appropriate considerations for initiation of PCI programs without on-site cardiac surgery. It is only appropriate to consider initiation of a PCI program without on-site cardiac surgical backup if this program will clearly fill a void in the healthcare needs of the community. Competition with another PCI program in the same geographic area, particularly an established program with surgical backup, may not be in the best interests of the community.

Tables 5 and 6 list the SCAI expert consensus document requirements for PCI programs without on-site surgical backup. Table 7 gives the requirements for primary PCI and emergency CABG at hospitals without on-site cardiac surgery, and Table 8 lists the requirements for patient and lesion selection and backup strategy for nonemergency PCI (352). TABLE 5. SCAI Expert Consensus Document Personnel and Facility Requirements for PCI Programs Without On-Site Surgical Backup

Experienced nursing and technical laboratory staff with training in interventional laboratories. Personnel must be comfortable treating acutely ill patients with hemodynamic and electrical instability.
On-call schedule with operation of laboratory 24 h/d, 365 d/y.*
Experienced coronary care unit nursing staff comfortable with invasive hemodynamic monitoring, operation of temporary pacemaker, and management of IABP. Personnel capable of endotracheal intubation and ventilator management both on-site and during transfer if necessary.
Full support from hospital administration in fulfilling the necessary institutional requirements, including appropriate support services (e.g., respiratory care, blood bank).
Written agreements for emergency transfer of patients to a facility with cardiac surgery. Transport protocols should be developed and tested a minimum of 2 times per year.
Well-equipped and maintained cardiac catheterization laboratory with high-resolution digital imaging capability and IABP equipment compatible with transport vehicles. The capability for real-time transfer of images and hemodynamic data (via T-1 transmission line) as well as audio and video images to review terminals for consultation at the facility providing surgical backup support is ideal.
Appropriate inventory of interventional equipment, including guide catheters, balloons, and stents in multiple sizes; thrombectomy and distal protection devices; covered stents; temporary pacemakers; and pericardiocentesis trays. Pressure wire device and IVUS equipment are optimal but not mandatory. Rotational or other atherectomy devices should be used cautiously in these facilities because of the greater risk of perforation.
Meticulous clinical and angiographic selection criteria for PCI (Tables 6 and 7).
Performance of primary PCI as the treatment of first choice for STEMI to ensure streamlined care paths and increased case volumes. Door-to-balloon times should be tracked, and <90 min outlier cases should be carefully reviewed for process improvement opportunities. On-site rigorous data collection, outcomes analysis, benchmarking, quality improvement, and formalized periodic case review.
Participation in a national data registry where available, such as the ACC NCDR in the United States.

*Required for U.S. facilities but may not be possible for all facilities worldwide.

ACC indicates American College of Cardiology; IABP, intra-aortic balloon pump; IVUS, intravascular ultrasound; NCDR, National Cardiovascular Data Registry; PCI, percutaneous coronary intervention; SCAI, Society for Cardiovascular Angiography and Interventions; and STEMI, ST-elevation myocardial infarction.

TABLE 6. SCAI Expert Consensus Document Requirements for Off-Site Surgical Backup

Interventional cardiologists establish a working relationship with cardiac surgeons at the receiving facility.
1. Cardiac surgeon must have privileges at the referring facility to allow review of treatment options as time allows.
2. Cardiac surgeon and receiving hospital agree to provide cardiac surgical backup for urgent cases at all hours and for elective cases at mutually agreed hours.
3. Surgeon and receiving facility ensure that patients will be accepted based on medical condition, capacity of surgeon to provide services at the time of request, and availability of resources. If this cannot be ensured before the start of an elective procedure, the case should not be done at this time.
4. Interventional cardiologists must review with surgeons the immediate needs and status of any patient transferred for urgent surgery.
5. Hospital administrations from both facilities endorse transfer agreement.
6. Transferring and receiving facilities establish a rigorous protocol for rapid transfer of patients, including the proper personnel with appropriate experience.
7. A transport provider is available to begin transport within 20 min of the request and provide vehicle/helicopter with necessary life-sustaining equipment, including IABP and monitoring capability.
8. Transferring physician obtains consent for surgery from patient or appropriate surrogate.
9. Initial informed consent for PCI discloses that the procedure is being done without on-site surgical backup and acknowledges the possibility of risks related to transfer. The consent process should include the risk of urgent surgery (approximately 0.3%) and state that a written plan for transfer exists.
10. As part of the local continuous quality improvement program, a regular review of all patients transferred for emergency surgery with the outcome of surgery and identification of any improvement opportunities.

IABP indicates intra-aortic balloon pump; PCI, percutaneous coronary intervention; and SCAI, Society for Cardiovascular Angiography and Interventions.

Adapted with permission from Dehmer et al. (352).

5. PROCEDURAL CONSIDERATIONS

5.1. Vascular Access: Recommendation

CLASS IIa

1. The use of radial artery access can be useful to decrease access site complications (255, 260, 356–362). *(Level of Evidence: A)*

See Online Data Supplement 21 for additional data regarding radial access.

Femoral artery access remains the most commonly used approach in patients undergoing PCI in the United States. Choosing a femoral artery puncture site is facilitated by fluoroscopic landmark identification or ultrasound guidance. Low punctures have a high incidence of peripheral artery complications, whereas high punctures have an increased risk of retroperitoneal hemorrhage. In patients with a synthetic graft, arterial access is possible after the graft is a few months old and complication rates are not increased (254).

Radial site access is used frequently in Europe and Canada but not in the United States (260). A learning curve exists for the radial approach that will affect procedure time and radiation dose, with a trend toward lower procedural success rates for radial versus femoral access (255). However, compared with femoral access, radial access decreases the rate of access-related bleeding and complications (255, 260, 363). In a recent large RCT comparing radial and femoral access in patients with ACS undergoing PCI, there was no difference in the primary composite endpoint (death, MI, stroke, major bleeding), although there was a lower rate of vascular complications with the use of radial access (362).

TABLE 7. SCAI Expert Consensus Document Requirements for Primary PCI and Emergency Aortocoronary Bypass Surgery at Hospitals Without On-Site Cardiac Surgery

Avoid intervention in patients with

- >50% diameter stenosis of left main artery proximal to infarct-related lesion, especially if the area in jeopardy is relatively small and overall LV function is not severely impaired
- Long, calcified, or severely angulated target lesions at high risk for PCI failure with TIMI flow grade 3 present during initial diagnostic angiography
- Lesions in other than the infarct artery (unless they appeared to be flow limiting in patients with hemodynamic instability or ongoing symptoms)
- Lesions with TIMI flow grade 3 that are not amenable to stenting in patients with left main or 3-vessel disease that will require coronary bypass surgery
- Culprit lesions in more distal branches jeopardizing only a modest amount of myocardium when there is more proximal disease that could be worsened by attempted intervention

Transfer emergently for coronary bypass surgery patients with

- High-grade left main or 3-vessel coronary disease with clinical or hemodynamic instability after successful or unsuccessful PCI of an occluded vessel and preferably with IABP support
- Failed or unstable PCI result and ongoing ischemia, with IABP support during transfer

IABP indicates intra-aortic balloon pump; LV, left ventricular; PCI, percutaneous coronary intervention; SCAI, Society for Cardiovascular Angiography and Interventions; and TIMI, Thrombolysis In Myocardial Infarction.

Adapted with permission from Dehmer et al. (352).

Radial artery access is particularly appealing in patients with coagulopathy, elevated international normalized ratio due to warfarin, or morbid obesity.

5.2. PCI in Specific Clinical Situations

5.2.1. UA/NSTEMI: Recommendations

CLASS I

1. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in UA/NSTEMI patients who have refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures) (207, 364, 365). *(Level of Evidence: B)*
2. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in initially stabilized UA/ NSTEMI patients (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events (207, 365–367). *(Level of Evidence: A)*
3. The selection of PCI or CABG as the means of revascularization in the patient with ACS should generally be based on the same considerations as those without ACS (53, 156, 207, 368). *(Level of Evidence: B)*

TABLE 8. SCAI Expert Consensus Document Requirements for Patient and Lesion Selection and Backup Strategy for Nonemergency PCI by Experienced Operators at Hospitals Without On-Site Cardiac Surgery

Patient risk: expected clinical risk in case of occlusion caused by procedure

High patient risk: Patients with any of the following:

- Decompensated congestive heart failure (Killip Class 3) without evidence for active ischemia, recent CVA, advanced malignancy, known clotting disorders
- LVEF <25%
- Left main stenosis (≥50% diameter) or 3-vessel disease unprotected by prior bypass surgery (>70% stenoses in the proximal segment of all major epicardial coronary arteries)
- Single-target lesion that jeopardizes >50% of remaining viable myocardium

Lesion risk: probability that procedure will cause acute vessel occlusion

Increased lesion risk: lesions in open vessels with any of the following characteristics:

- Diffuse disease (>2 cm in length) and excessive tortuosity of proximal segments
- More than moderate calcification of a stenosis or proximal segment
- Location in an extremely angulated segment (>90%)
- Inability to protect major side branches
- Degenerated older vein grafts with friable lesions
- Substantial thrombus in the vessel or at the lesion site
- Any other feature that may, in the operator's judgment, impede successful stent deployment Aggressive measures to open CTOs are also discouraged because of an increased risk of perforation.

Strategy for surgical backup based on lesion and patient risk:

- **High-risk patients with high-risk lesions** should not undergo nonemergency PCI at a facility without on-site surgery.
- **High-risk patients with non-high-risk lesions:** Nonemergency patients with this profile may undergo PCI, but confirmation that a cardiac surgeon and operating room are immediately available is necessary.
- **Non-high-risk patients with high-risk lesions** require no additional precautions.
- **Non-high-risk patients with non-high-risk lesions** require no additional precautions. Best scenario for PCI without on-site surgery.

CTO indicates chronic total occlusion; CVA, cerebrovascular accident; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; and SCAI, Society for Cardiovascular Angiography and Interventions.

Adapted with permission from Dehmer et al. (352).

CLASS III: NO BENEFIT

1. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with extensive comorbidities (e.g., liver or pulmonary failure, cancer) in whom *(Level of Evidence: C)*
   a. The risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization,
   b. There is a low likelihood of ACS despite acute chest pain, or
   c. Consent to revascularization will not be granted regardless of the findings.

The goals of coronary angiography and revascularization in UA/NSTEMI patients are to reduce the risk of death and MI and provide symptom relief. To improve prognosis, early risk stratification is essential for selection of medical and/or invasive treatment strategies. Indications for revascularization depend on the patient's clinical risk characteristics and coronary anatomy and are in general stronger in the presence of high-risk clinical presentation (e.g., dynamic electrocardiogram [ECG] changes, elevated troponin, high Global Registry of Acute Coronary Events score), recurrent symptoms, threatened viable myocardium, CKD, and larger ischemic burden (Appendix 4E). For choice of revascularization technique, the anatomical considerations are generally those used for stable CAD, although PCI may initially be performed in the index lesion to stabilize the patient (Section 2).

Contemporary studies variably comparing strategies of very early (within hours of admission), early (within 24 hours of admission), and delayed (1 to 7 days after admission) cardiac catheterization and revascularization support a strategy of *early* angiography and revascularization to reduce the risk of recurrent ischemia and MI, particularly among those at high risk (e.g., Global Registry of Acute Coronary Events score >140) (367, 369, 370), whereas a delayed approach is reasonable in low-intermediate risk patients (based on clinical course). There is no evidence that incremental benefit is derived by angiography and PCI performed within the first few hours of hospital admission (207, 367, 371–378).

5.2.2. ST-Elevation Myocardial Infarction

5.2.2.1. CORONARY ANGIOGRAPHY STRATEGIES IN STEMI: RECOMMENDATIONS

CLASS I

1. A strategy of immediate coronary angiography with intent to perform PCI (or emergency CABG) in patients with STEMI is recommended for
   a. Patients who are candidates for primary PCI (351, 379–382). *(Level of Evidence: A)*
   b. Patients with severe heart failure or cardiogenic shock who are suitable candidates for revascularization (383, 384). *(Level of Evidence: B)*

CLASS IIa

1. A strategy of immediate coronary angiography (or transfer for immediate coronary angiography) with intent to perform PCI is reasonable for patients with STEMI, a moderate to large area of myocardium at risk, and evidence of failed fibrinolysis (385, 386). *(Level of Evidence: B)*
2. A strategy of coronary angiography (or transfer for coronary angiography) 3 to 24 hours after initiating fibrinolytic therapy with intent to perform PCI is reasonable for hemodynamically stable patients with STEMI and evidence for successful fibrinolysis when angiography and revascularization can be performed as soon as logistically feasible in this time frame (387–391). *(Level of Evidence: A)*

CLASS IIb

1. A strategy of coronary angiography performed before hospital discharge might be reasonable in stable patients with STEMI who did not undergo cardiac catheterization within 24 hours of STEMI onset. *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. A strategy of coronary angiography with intent to perform PCI is not recommended in patients with STEMI in whom the risks of revascularization are likely to outweigh the benefits or when the patient or designee does not want invasive care. *(Level of Evidence: C)*

The historical reperfusion strategies of "primary PCI," "immediate PCI," "rescue PCI," "deferred PCI," "facilitated PCI," and the "pharmacoinvasive strategy" have evolved in parallel with advances in antithrombotic therapy and STEMI prehospital and hospital systems of care. The clinical challenge in primary PCI is achieving rapid time to treatment and increasing patient access to this preferred reperfusion strategy. The clinical challenge in patients treated with fibrinolytic therapy is deciding for whom and when to perform coronary angiography.

In unstable patients (e.g., severe heart failure or cardiogenic shock, hemodynamically compromising ventricular arrhythmias) not treated initially with primary PCI, a strategy of immediate coronary angiography with intent to perform PCI is implemented unless invasive management is considered futile or unsuitable given the clinical circumstances (383, 384).

In stable patients treated with fibrinolytic therapy and clinical suspicion of reperfusion failure, a strategy of immediate coronary angiography followed by PCI improves outcome in those at high risk (385, 386). Such a strategy is also implemented in patients with evidence for infarct artery reocclusion (Table 9). The T9
clinical diagnosis of failed fibrinolysis is difficult but is best made when there is <50% ST-segment resolution 90 minutes after initiation of therapy in the lead showing the greatest degree of ST-segment elevation at presentation. Given the association between bleeding events and adverse cardiac events, a reasonable approach is to select moderate- and high-risk patients for PCI and treat low-risk patients with medical therapy. ECG and clinical findings of anterior MI or

TABLE 9. Indications for Coronary Angiography in STEMI

Coronary angiography at any time			
Patients in whom the risks of revascularization are likely to outweigh the benefits or the patient or designee does not want invasive care	III: No Benefit	C	N/A

COR indicates class of recommendation; LOE, level of evidence; N/A, not applicable; PCI, percutaneous coronary intervention; and STEMI, ST-elevation myocardial infarction.

inferior MI with right ventricular involvement or precordial ST-segment depression, as well as ongoing pain, usually predicts increased risk and the greatest potential benefit (392). Conversely, patients with symptom resolution, improving ST-segment elevation, or inferior MI localized to 3 ECG leads probably gain little benefit.

In stable patients treated with fibrinolytic therapy and clinical evidence for successful reperfusion, an early invasive strategy with cardiac catheterization performed within 24 hours decreases reinfarction and recurrent ischemic events (388, 390, 391). Because of the associated increased bleeding risk, very early (<2 to 3 hours) catheterization after administration of fibrinolytic therapy with intent to perform revascularization should be reserved for patients with evidence of failed fibrinolysis and significant myocardial jeopardy for whom immediate angiography and revascularization would be appropriate (393).

5.2.2.2. PRIMARY PCI OF THE INFARCT ARTERY: RECOMMENDATIONS

CLASS I

1. Primary PCI should be performed in patients within 12 hours of onset of STEMI (379–382). *(Level of Evidence: A)*
2. Primary PCI should be performed in patients with STEMI presenting to a hospital with PCI capability within 90 minutes of first medical contact as a systems goal (394, 395). *(Level of Evidence: B)*
3. Primary PCI should be performed in patients with STEMI presenting to a hospital without PCI capability within 120 minutes of first medical contact as a systems goal (396–398). *(Level of Evidence: B)*
4. Primary PCI should be performed in patients with STEMI who develop severe heart failure or cardiogenic shock and are suitable candidates for revascularization as soon as possible, irrespective of time delay (383, 384). *(Level of Evidence: B)*
5. Primary PCI should be performed as soon as possible in patients with STEMI and contraindications to fibrinolytic therapy with isch-emic symptoms for less than 12 hours (399, 400). *(Level of Evidence: B)*

CLASS IIa

1. Primary PCI is reasonable in patients with STEMI if there is clinical and/or electrocardiographic evidence of ongoing ischemia between 12 and 24 hours after symptom onset (401–403). *(Level of Evidence: B)*

CLASS IIb

1. Primary PCI might be considered in asymptomatic patients with STEMI and higher risk presenting between 12 and 24 hours after symptom onset. *(Level of Evidence: C)*

CLASS III: HARM

1. PCI should not be performed in a noninfarct artery at the time of primary PCI in patients with STEMI without hemodynamic compromise (404–408). *(Level of Evidence: B)*

Primary PCI is preferred to fibrinolytic therapy when time-to-treatment delays are short and the patient presents to a high-volume, well-equipped center staffed with expert interventional cardiologists and skilled support staff. Compared with fibrinolytic therapy in RCTs, primary PCI produces higher rates for infarct artery patency, TIMI flow grade 3, and lower rates for recurrent ischemia, reinfarction, emergency repeat revascularization procedures, intracranial hemorrhage, and death (379). Early, successful PCI also greatly decreases the complications of STEMI that result from longer ischemic times or unsuccessful fibrinolytic therapy, allowing earlier hospital discharge and resumption of daily activities. The greatest

*Systems goal of performing primary PCI within 90 min of first medical contact when the patient presents to a hospital with PCI capability (394, 395)(Class *I; LOE: B)* and within 120 min when the patient presents to a hospital without PCI capability (396–398) (Class *I; LOE:* B).
COR indicates class of recommendation; LOE, level of evidence; N/A, not applicable; PCI, percutaneous coronary intervention; and STEMI, ST-elevation myocardial infarction.

mortality benefit of primary PCI is in high-risk patients. PCI outcomes may not be as successful with prolonged time-to-treatment or low-volume hospitals and operators (Table 10).

Several reports have shown excellent outcomes for patients with STEMI undergoing interhospital transfer where first medical contact-to-door balloon time modestly exceeded the systematic goal of <90 minutes (396–398, 409). In these reports, the referring hospital and the receiving hospital established a transfer protocol that minimized transfer delays, and outcomes were similar to those of direct-admission patients. On the basis of these results, the PCI and STEMI guideline writing committees have modified the first medical contact-to-device time goal from 90 minutes to 120 minutes for interhospital transfer patients (397), while emphasizing that systems should continue to strive for times ≤90 minutes. Hospitals that cannot meet these criteria should use fibrinolytic therapy as their primary reperfusion strategy.

PCI of a noninfarct artery at the time of primary PCI in stable patients is associated with worse clinical outcomes unless the patient is in cardiogenic shock where PCI of a severe stenosis in a coronary artery supplying a large territory of myocardium might improve hemodynamic stability (404, 406, 408). Delayed PCI can be performed in noninfarct arteries at a later time if clinically indicated (410–412).

5.2.2.3. DELAYED OR ELECTIVE PCI IN PATIENTS WITH STEMI: RECOMMENDATIONS

CLASS IIa

1. PCI is reasonable in patients with STEMI and clinical evidence for fibrinolytic failure or infarct artery reocclusion (385, 386). *(Level of Evidence: B)*
2. PCI is reasonable in patients with STEMI and a patent infarct artery 3 to 24 hours after fibrinolytic therapy (390, 391). *(Level of Evidence: B)*
3. PCI is reasonable in patients with STEMI who demonstrate ischemia on noninvasive testing (410, 411). *(Level of Evidence: B)*

CLASS IIb

1. PCI of a hemodynamically significant stenosis in a patent infarct artery greater than 24 hours after STEMI may be considered as part of an invasive strategy (413–417). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. PCI of a totally occluded infarct artery greater than 24 hours after STEMI should not be performed in asymptomatic patients with 1- or 2-vessel disease if patients are hemodynamically and electrically stable and do not have evidence of severe ischemia (418–420). *(Level of Evidence: B)*

Studies and meta-analyses suggest potential benefit for PCI in fibrinolytic failure (385, 386). In stable

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

patients treated with fibrinolytic therapy and clinical evidence for successful reperfusion, an early invasive strategy with cardiac catheter-ization performed within 24 hours decreases reinfarction and recurrent ischemic events (388, 390, 391).

PCI for a hemodynamically significant stenosis in a patent infarct artery >24 hours after STEMI as part of a revascularization strategy improves outcome (410, 411, 413–417). PCI of an occluded infarct artery 1 to 28 days after MI in asymptomatic patients without evidence of myocardial ischemia has no incremental benefit beyond optimal medical therapy with aspirin, beta blockers, angiotensin-converting enzyme inhibitors, and statins in preserving LV function and preventing subsequent cardiovascular events (418–420). It is important to note that elective PCI of an occluded infarct artery has not been studied in patients with New York Heart Association functional class III or IV heart failure, rest angina, serum creatinine >2.5 mg/dL, left main or 3-vessel CAD, clinical instability, or severe inducible ischemia on stress testing in an infarct zone that is not akinetic or dyskinetic.

5.2.3. Cardiogenic Shock: Recommendations

CLASS I

1. PCI is recommended for patients with acute MI who develop cardiogenic shock and are suitable candidates (384, 421–423). *(Level of Evidence: B)*
2. A hemodynamic support device is recommended for patients with cardiogenic shock after STEMI who do not quickly stabilize with pharmacological therapy (384, 424–427). *(Level of Evidence: B)*

See Online Data Supplement 22 for additional data regarding cardiogenic shock.

Cardiogenic shock is the leading cause of in-hospital mortality complicating STEMI. Revascularization is the only treatment proven to decrease mortality rates (384, 421–423). Although revascularization is almost always accomplished through PCI, selected patients with severe 3-vessel or left main disease can benefit from emergency CABG. Revascu-larization attempts may be futile and not indicated in cases of severe multiorgan failure (427). Patient selection for revascularization is more important in the elderly, but several observational reports demonstrate acceptable outcomes in patients with few comorbidities and a reasonable potential for survival (428–431). Patients who present to hospitals without PCI capability are usually emergently transported to a PCI center, because mortality without transfer is markedly elevated (432).

5.2.3.1. PROCEDURAL CONSIDERATIONS FOR CARDIOGENIC SHOCK. Patients with cardiogenic shock should receive standard pharmacological therapies, including aspirin, a $P2Y_{12}$ receptor antagonist, and anticoagulation (427, 433). Inotropic and vasopressor therapy improves perfusion pressure. Historically, negative inotropes and vasodilators are avoided. IV GP IIb/IIIa inhibitors have been shown to provide benefit in observational studies but not in 1 small RCT (433).

Endotracheal intubation and mechanical ventilation with positive end-expiratory pressure is usually necessary in patients with respiratory failure. Placement of a temporary pacemaker is indicated for patients with bradycardia or high-degree atrioventricular heart block. A pulmonary artery catheter can provide information to dose and titrate inotropes and pressors. Further hemodynamic support is available with IABP counterpulsation or percutaneous LV assist devices, although no data support a reduction in mortality rates (434).

Contrast medium injections should be minimized. Orthogonal angiograms of the left coronary artery and a left anterior oblique angiogram of the right coronary artery are usually sufficient to identify the infarct artery (435). Although most patients undergoing revascularization will receive a stent as part of the procedure, there are conflicting data on the impact of stenting over balloon angioplasty. Some studies reveal lower mortality rates (436–438), whereas others reveal no benefit (439) or higher mortality rates (440). There are no data comparing the choice ofBMS versus DES in cardiogenic shock; however, BMS are often used because compliance with long-term DAPT is often unclear in the emergency setting.

In patients with multivessel disease, revascularization of the noninfarct artery may be necessary to maximize myocardial perfusion. Alternatively, in patients with multivessel disease and particularly left main disease, emergency CABG as a primary reperfusion strategy may be preferred (50, 441). Refractory cardiogenic shock unresponsive to revascularization may necessitate institution of more intensive cardiac support with a ventricular assist device or other hemodynamic support devices to allow for myocardial recovery or subsequent cardiac transplantation in suitable patients.

5.2.4. Revascularization Before Noncardiac Surgery: Recommendations

CLASS IIa

1. For patients who require PCI and are scheduled for elective noncardiac surgery in the subsequent 12 months, a strategy of balloon angioplasty, or BMS implantation followed by 4 to 6 weeks of DAPT, is reasonable (442–448). *(Level of Evidence: B)*
2. For patients with DES who must undergo urgent surgical procedures that mandate the discontinuation of DAPT, it is reasonable to continue aspirin if possible and restart the $P2Y_{12}$ inhibitor as soon as possible in the immediate postoperative period (444). *(Level of Evidence: C)*

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 31

CLASS III: HARM

1. Routine prophylactic coronary revascularization should not be performed in patients with stable CAD before noncardiac surgery (449, 450). *(Level of Evidence: B)*
2. Elective noncardiac surgery should not be performed in the 4 to 6 weeks after balloon angioplasty or BMS implantation or the 12 months after DES implantation in patients in whom the $P2Y_{12}$ inhibitor will need to be discontinued perioperatively (208, 447, 451, 452). *(Level of Evidence: B)*

The 2007 and 2009 ACC/AHA Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery gave detailed recommendations for the evaluation of patients undergoing noncardiac surgery (444). Patients with evidence of ACS should receive standard therapy, including early revascularization, to minimize the risk of adverse events. Patients with known significant left main or 3-vessel CAD who would otherwise benefit from revascularization in terms of survival or symptomatic relief also generally undergo revascularization before elective noncardiac surgery.

Two RCTs (449, 450) found no benefit with routine preoperative revascularization before noncardiac surgery. Noncardiac surgery early after coronary stenting, particularly in the first 4 weeks, is associated with a high risk of stent thrombosis and death (444, 446, 448). When emergency surgery is necessary, the patient should proceed to surgery without prior PCI. When surgery is required within 30 days and coronary revascularization is required before surgery, many clinicians perform balloon angioplasty alone to avoid the need for DAPT. In situations where preoperative revascularization is required and surgery can be deferred for at least 30 days, many clinicians use BMS and discontinue DAPT after 30 days. If surgery is elective and can be deferred for 1 year, most clinicians would consider DES to reduce the long-term risk of restenosis. A dilemma occurs when a patient has undergone PCI and then unexpectedly requires noncardiac surgery. Many patients can undergo surgery on DAPT, where the risk-benefit ratio will favor continued dual antiplatelet inhibition. If it is necessary to hold $P2Y_{12}$ inhibitor therapy, most clinicians will still continue aspirin uninterrupted during the perioperative period if the bleeding risk is not prohibitive. When the risk of delaying surgery or performing surgery while the patient is on DAPT exceeds the risk of stent thrombosis from stopping DAPT, the $P2Y_{12}$ inhibitor is stopped before surgery and resumed as soon as possible afterward. No $P2Y_12$ inhibitor "bridging" strategy (e.g., GP IIb/IIIa inhibitor, antithrombin therapy) has been validated.

5.3. Coronary Stents: Recommendations

CLASS I

1. Before implantation of DES, the interventional cardiologist should discuss with the patient the need for and duration of DAPT and the ability of the patient to comply with and tolerate DAPT (212). *(Level of Evidence: C)*
2. DES are useful as an alternative to BMS to reduce the risk of restenosis in cases in which the risk of restenosis is increased and the patient is likely to be able to tolerate and comply with prolonged DAPT *(Level of Evidence: A for elective PCI* [453,453a,454–456]; *Level of Evidence: C for UA/NSTEMI* (453); *Level of Evidence: A for STEMI* [453,456–459]).
3. Balloon angioplasty or BMS should be used in patients with high bleeding risk, inability to comply with 12 months of DAPT, or anticipated invasive or surgical procedures within the next 12 months, during which time DAPT may be interrupted (208, 460–462). *(Level of Evidence: B)*

CLASS III: HARM

1. PCI with coronary stenting should not be performed if the patient is not likely to be able to tolerate and comply with DAPT (208–211). *(Level of Evidence: B)*
2. DES should not be implanted if the patient is not likely to be able to tolerate and comply with prolonged DAPT or this cannot be determined before stent implantation (208, 460–462). *(Level of Evidence: B)*

Coronary stent implantation is commonly performed during PCI to prevent recoil, abrupt closure, and late restenosis (463, 464). BMS are composed of either stainless steel or cobalt chromium alloys. Because the risk of stent thrombosis is greatest within the first 30 days after implantation, the use of DAPT is required for 30 days after implantation of BMS (208).

In the United States, 4 types of DES are currently approved: sirolimus-eluting stents, paclitaxel-eluting stents, zotarolimus-eluting stents, and everolimus-eluting stents. DES vary according to stent scaffold material and design, drug content, and the polymer used for drug elution; however, several common clinical features are present. First, sirolimus-eluting stents, paclitaxel-eluting stents, and zotarolimus-eluting stents have been demonstrated in RCTs to be associated with a reduced need for repeat revascularization and no increase in death or MI compared with BMS at 4 years' follow-up (465). Everolimus-eluting stents have been demonstrated in RCTs to be associated with a lower need for repeat revascularization than paclitaxel-

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

eluting stents, and, by inference, a lower risk for repeat revascularization than BMS (466, 467), with no increase in death or MI at 2-year follow-up (468). Second, each of these stents is presumed to be associated with delayed healing based on pathologic studies and longer periods of risk for thrombosis compared with BMS and require longer duration of DAPT (469). In the RCTs that led to the U.S. Food and Drug Administration (FDA) approval of these stents, the recommended minimum duration of DAPT therapy was 3 to 6 months. Recently, the consensus of clinical practice has been 12 months of DAPT following DES implantation to avoid late (after 30 days) thrombosis (208), based on observational studies of paclitaxel-eluting stents and sirolimus-eluting stents that indicate lower risk of late stent thrombosis with >6 months of therapy (212). Extending DAPT beyond 1 year is considered reasonable by some practitioners based on observational data analysis (212), but RCTs to determine whether longer DAPT is associated with reduction in stent thrombosis risk have not been completed. Finally, DES therapy is more expensive than BMS. Cost-effectiveness analysis has shown a reduction in total cost associated with DES because of avoidance of repeat procedures, yet it may be reasonable to consider use of BMS in patient subsets in which the risk of restenosis is low (470).

This risk-benefit profile is most favorable for DES over BMS when the risk of restenosis with BMS is high (Table 11). Pooled and meta-analyses have demonstrated that in patients with diabetes, use of DES decreases the risk of restenosis compared with BMS (471, 472). DES may be more appealing for unprotected left main PCI, given the rate and clinical consequences of restenosis in this location (473–475). The risk of stent thrombosis is higher in populations or lesion types excluded from RCTs of DES (e.g., STEMI, smaller arteries [<2.5 mm diameter], longer lesions, bifurcations) (210, 465). Importantly, these features also predict both stent thrombosis (476) and restenosis in BMS (477). The greatest risk of stent thrombosis is within the first year, ranging from 0.7% to 2.0%, depending on patient and lesion complexity. Late stent thrombosis risk after 1 year with DES is observed at a rate of 0.2% to 0.4% per year (210, 478).

Compared with balloon angioplasty, routine BMS implantation during primary PCI decreases risk for target-vessel revascularization and possibly reduces MI rates but does not reduce mortality rates (479). More recent primary PCI studies and meta-analyses have demonstrated lower restenosis rates without increased risk of adverse stent outcome with DES compared with BMS. Although stent thrombosis rates in trials ofSTEMI are higher than in trials of elective PCI, the rates of stent thrombosis are not higher with DES compared with BMS in STEMI (453, 456–459).

TABLE 11. Clinical Situations Associated With DES or BMS Selection Preference

DES Generally Preferred Over BMS (Efficacy Considerations)	BMS Preferred Over DES (Safety Considerations)
• Left main disease	• Unable to tolerate or comply with DAPT
• Small vessels	• Anticipated surgery requiring discontinuation of DAPT within 12 mo
• In-stent restenosis	• High risk of bleeding
• Bifurcations	
• Diabetes	
• Long lesions	
• Multiple lesions	
• Saphenous vein grafts	

BMS indicates bare-mental stent(s); DAPT, dual antiplatelet therapy; and DES, drug-eluting stent(s).

The greatest risk for DES thrombosis is early discontinuation of DAPT (208, 460–462). It is therefore important to determine that the patient will likely be able to tolerate and comply with DAPT before implantation of DES. Therefore, DES should not be used in the presence of financial barriers to continuing prolonged DAPT, social barriers that may limit patient compliance, or medical issues involving bleeding risks or the need for invasive or surgical procedures in the following year that would interrupt antiplatelet therapy. The need for use of long-term warfarin and the associated increased risk ofbleeding with long-term "triple therapy" is also a consideration in deciding on DES versus BMS (480).

Patients implanted with most contemporary coronary stents can undergo magnetic resonance imaging (MRI) examination any time after implantation (481, 482). The effect of the MRI examination on heating of the drug or polymer coating used in DES is unknown. There is no indication for antibiotic prophylaxis before dental or invasive procedures in patients with coronary stents (483).

5.4. Adjunctive Diagnostic Devices

5.4.1. FFR: Recommendation

CLASS IIa

1. FFR is reasonable to assess angiographic intermediate coronary lesions (50% to 70% diameter stenosis) and can be useful for guiding revascularization decisions in patients with SIHD (12, 97, 484–486). *(Level of Evidence: A)*

See Online Data Supplement 23 for additional data regarding FFR.

The limitations of coronary angiography for determination of lesion severity have been well described. Angiography may under- or overestimate lesion stenosis. Various physiologic measurements can be made in the catheterization laboratory, including

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

coronary flow reserve and FFR. The correlation of ischemia on stress testing with FFR values of <0.75 has been established in numerous comparative studies with high sensitivity (88%), specificity (100%), positive predictive value (100%), and overall accuracy (93%) (487). The 5-year outcomes for patients with medical therapy based on an FFR >0.75 were superior compared with PCI in the DEFER (Deferral Versus Performance of Balloon Angioplasty in Patients Without Documented Ischemia) study (485). The FAME (Fractional Flow Reserve Versus Angiography for Multivessel Evaluation) study identified the benefit for deferring PCI in patients with multivessel disease and lesion FFR >0.80, with reduced rates of cardiac events at both 1 and 2 years (97, 486). Whereas both FFR and IVUS have been used for assessment of intermediate angiographic stenosis with favorable outcomes, FFR may reduce the need for revascularization when compared with IVUS (488). Although IVUS is often considered in the assessment ofequivocal left main stenosis, FFR may be similarly effective (484).

5.4.2. IVUS: Recommendations

CLASS IIa

1. IVUS is reasonable for the assessment of angiographically indeterminant left main CAD (489–491). *(Level of Evidence: B)*
2. IVUS and coronary angiography are reasonable 4 to 6 weeks and 1 year after cardiac transplantation to exclude donor CAD, detect rapidly progressive cardiac allograft vasculopathy, and provide prognostic information (492–494). *(Level of Evidence: B)*
3. IVUS is reasonable to determine the mechanism of stent restenosis (495). *(Level of Evidence: C)*

CLASS IIb

1. IVUS may be reasonable for the assessment of non-left main coronary arteries with angiographically intermediate coronary stenoses (50% to 70% diameter stenosis) (489, 496, 497). *(Level of Evidence: B)*
2. IVUS may be considered for guidance of coronary stent implantation, particularly in cases of left main coronary artery stenting (490, 495, 498). *(Level of Evidence: B)*
3. IVUS may be reasonable to determine the mechanism of stent thrombosis (495). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. IVUS for routine lesion assessment is not recommended when revascularization with PCI or CABG is not being contemplated. *(Level of Evidence: C)*

IVUS provides a unique coronary artery assessment of lesion characteristics, minimal and maximal lumen diameters, cross-sectional area, and plaque area. Diagnostic uses for IVUS include the assessment of angiographic indeterminant coronary artery stenoses, determination of the mechanism of stent restenosis or thrombosis, and postcardiac transplantation surveillance of CAD (488, 490–492, 499). For left main coronary artery stenoses, a minimal lumen diameter of <2.8 mm or a minimal lumen area of <6mm^2 suggests a physiologically significant lesion for which patients may benefit from revascularization. A minimal lumen area >7.5 mm^2 suggests that revascularization may be safely deferred (490). A minimal lumen area between 6 and 7.5 mm^2 requires further physiological assessment, such as measurement of FFR (487, 500). For non-left main stenoses, minimal lumen diameter >2.0 mm and minimal lumen area > 4.0 mm^2 correlate with low event rates (489). However, in smaller-diameter arteries (minimal lumen area <3.0 mm^2), measurement of FFR may more accurately reflect a significant stenosis (488). Studies correlating IVUS measures with ischemia have not specified the size of coronary arteries for which such correlations are valid (488, 489, 497).

IVUS assessment after stent thrombosis may serve to identify stent underexpansion or malapposition (499). IVUS is superior to angiography in the early detection of the diffuse, immune-mediated, cardiac allograft vasculopathy; recommendations about the use of IVUS for this purpose were published in 2010 by the International Society of Heart and Lung Transplantation (492). Whereas IVUS has been an important research tool in interventional cardiology, most clinical studies of IVUS have not been able to demonstrate that its routine use results in a reduction of MACE or restenosis rates (498, 501, 502). IVUS has been inappropriately used in clinical practice to justify implanting stents in mildly diseased segments that may require no intervention (503).

5.4.3. Optical Coherence Tomography. Compared with IVUS, optical coherence tomography has greater resolution (10 to 20 micronmeter axially) but more limited depth of imaging (1 to 1.5 mm) (504, 505). Unlike IVUS, optical coherence tomography requires that the artery be perfused with saline solution or crystalloid during image acquisition and therefore does not permit imaging of ostial lesions. Clinical studies have shown low optical coherence tomography complication rates (506, 507), similar to those of IVUS (508). The excellent resolution of optical coherence tomography permits detailed in vivo 2-dimensional imaging of plaque morphological characteristics (e.g., calcification, lipid, thrombus, fibrous cap thickness, and plaque ulceration or rupture) (508–510) and evaluation of the arterial response to stent implantation (e.g., stent strut neointimal thickness and apposition) (511–513) and

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

may be of value in clinical research. The appropriate role for optical coherence tomography in routine clinical decision making has not been established.

5.5. Adjunctive Therapeutic Devices

5.5.1. Coronary Atherectomy: Recommendations

CLASS IIa

1. Rotational atherectomy is reasonable for fibrotic or heavily calcified lesions that might not be crossed by a balloon catheter or adequately dilated before stent implantation (514, 515). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Rotational atherectomy should not be performed routinely for de novo lesions or in-stent restenosis (516–519). *(Level of Evidence: A)*

Rotational atherectomy in RCTs was associated with higher rates of MACE at 30 days and no reduction in restenosis. It has a limited role in facilitating the dilation or stenting of lesions that cannot be crossed or expanded with PCI (520, 521). Devices for directional coronary atherectomy are no longer marketed in the United States.

5.5.2. Thrombectomy: Recommendation

CLASS IIa

1. Aspiration thrombectomy is reasonable for patients undergoing primary PCI (522–524). *(Level of Evidence: B)*

The benefit of thrombectomy in patients with STEMI appears to be dependent on the type of thrombectomy technique used (522–526). No clinical benefit for routine rheolytic thrombectomy (AngioJet device, MEDRAD Interventional, Minneapolis, MN and Pittsburgh, PA) has been demonstrated in primary PCI (524–526). Two RCTs (522, 523) and a meta-analysis (524) support the use of manual aspiration thrombectomy during primary PCI to improve microvascular reperfusion and decrease MACE. It is not known whether a strategy of selective thrombus aspiration in patients with a large thrombus burden might be equivalent to routine thrombus aspiration.

5.5.3. Laser Angioplasty: Recommendations

CLASS IIb

1. Laser angioplasty might be considered for fibrotic or moderately calcified lesions that cannot be crossed or dilated with conventional balloon angioplasty (527). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Laser angioplasty should not be used routinely during PCI (516, 518, 528). *(Level of Evidence: A)*

RCTs of laser angioplasty have not demonstrated improved clinical or angiographic PCI outcomes, although some practitioners think that laser angioplasty may be of use in the treatment of lesions that are difficult to dilate with balloon angioplasty (527).

5.5.4. Cutting Balloon Angioplasty: Recommendations

CLASS IIb

1. Cutting balloon angioplasty might be considered to avoid slippage-induced coronary artery trauma during PCI for in-stent restenosis or ostial lesions in side branches (529). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Cutting balloon angioplasty should not be performed routinely during PCI (516, 529, 530). *(Level of Evidence: A)*

Although some small, single-center trials have suggested that cutting balloon angioplasty was more efficacious than balloon angioplasty, it was not found to be safer or more effective in several large trials (516, 529, 531). When balloon dilation is required for in-stent restenosis, however, cutting balloons are less likely to slip and may offer a technical advantage over conventional balloons (529). Scoring balloons have been used by some cardiologists as an alternative to cutting balloons, but no RCTs have been reported (531).

5.5.5. Embolic Protection Devices: Recommendation

CLASS I

1. Embolic protection devices (EPDs) should be used during saphenous vein graft (SVG) PCI when technically feasible (532–535). *(Level of Evidence: B)*

The incidence of MACE doubles in SVG PCI compared with native-artery PCI (536). A distal balloon occlusion EPD decreased the 30-day composite outcome of death, MI, emergency CABG, or target-lesion revascularization (9.6% versus 16.5%) in the only RCT (532). Subsequent noninferiority comparisons have demonstrated similar benefit with proximal occlusion and distal filter EPDs, with benefit limited to reduction in periprocedural MI (534, 535) (Section 5.10). Distal EPDs do not improve survival or reinfarction rates in patients undergoing native-artery PCI (524, 537).

5.6. Percutaneous Hemodynamic Support Devices: Recommendation

CLASS IIb

1. Elective insertion of an appropriate hemodynamic support device as an adjunct to PCI may be

reasonable in carefully selected high-risk patients. *(Level of Evidence: C)*

IABP counterpulsation is frequently used as an adjunct to PCI in hemodynamically unstable patients (538, 539). In single-center series, the routine prophylactic use of IABP during PCI in high-risk patients was associated with lower mortality and fewer major complications compared with rescue use of IABP (540, 541). In the only RCT in high-risk PCI patients (BCIS-1 [Balloon Pump-Assisted Coronary Intervention Study]) (542), there was no difference in the primary composite outcome between routine and provisional use of IABP. There were also no differences in major secondary endpoints except major procedural complications (e.g., prolonged hypotension, ventricular tachycardia/ fibrillation, cardiopulmonary arrest), which were lower in the routine IABP group. Bleeding and access site complication rates tended to be higher in the routine IABP group. The "bailout" rate of IABP insertion in the provisional IABP group was 12%, mostly for procedural hypotension (542). A meta-analysis of IABP therapy in patients with STEMI did not show improved outcomes with the use of IABP (434).

The Impella Recover LP 2.5 System (Abiomed, Aachen, Germany/Danvers, Massachusetts) is a 12.5 Fr catheter that is inserted percutaneously through a 13 Fr femoral artery sheath and placed across the aortic valve into the left ventricle, through which a transaxial blood pump provides flows of up to 2.5 L/min. This has been used in patients with cardiogenic shock (543, 544) as well as elective PCI (545). The hemodynamic effects of the Impella 2.5 have been studied in high-risk PCI patients, demonstrating beneficial LV unloading effect (decreased end-diastolic pressure and wall stress) with no change in global or systolic LV function (546). The PROTECT I (A Prospective Feasibility Trial Investigating the Use of the IMPELLA Recover LP 2.5 System in Patients Undergoing High-Risk PCI) trial in 20 patients undergoing high-risk PCI with the Impella 2.5 system concluded that this device was safe, easy to implant, and hemodynamically effective (547). The Europella Registry included 144 patients undergoing high-risk PCI and reported the safety, feasibility, and potential usefulness of the device and that RCTs were warranted (548). The randomized PROTECT II (A Prospective, Multicenter, Randomized Controlled Trial of the IMPELLA Recover LP 2.5 System Versus Intra Aortic Balloon Pump in Patients Undergoing Non Emergent High Risk PCI) trial, which was designed to demonstrate superiority ofImpella over IABP in terms of 1-month adverse events, was halted for futility after interim analysis of study results (549).

The TandemHeart (CardiacAssist, Inc, Pittsburgh, PA) is a left atrial to aorta catheter-based system that includes a centrifugal blood pump providing flows of up to 4 L/min. This device uses a 21 Fr cannula percutaneously inserted into the femoral vein for transseptal access of the left atrium with a 15 Fr catheter placed in the contralateral femoral artery and positioned above the aortic bifurcation. An extracorporeal pump then returns oxygenated blood from the left atrium to the arterial system, thereby unloading the left ventricle (550, 551). The hemodynamic effects have been studied in patients undergoing high-risk PCI (552). Several small studies have addressed the clinical efficacy of the TandemHeart in high-risk patients undergoing PCI (551, 553–556). In a single-center report of 68 patients undergoing high-risk PCI using either TandemHeart or Impella Recover 2.5, success rates (>90%) and vascular complications (7%) were similar (553).

High-risk patients may include those undergoing unprotected left main or last-remaining-conduit PCI, those with severely depressed EF undergoing PCI of a vessel supplying a large territory, and/or those with cardiogenic shock. Patient risk, hemodynamic support, ease of application/ removal, and operator and laboratory expertise are all factors involved in consideration of use of these devices. With devices that require large cannula insertion, the risk of vascular injury and related complications are important considerations regarding necessity and choice of device.

5.7. Interventional Pharmacotherapy

5.7.1. Procedural Sedation. The term *conscious sedation* is falling out of favor with the recognition that there is a spectrum of procedural sedation levels. Most patients undergoing PCI fall under the definition of either minimal sedation (anxiolysis) or moderate sedation (depressed consciousness with the ability to respond purposefully to verbal commands) (557). Nonetheless, an underlying principle of procedural sedation is that the physician should be prepared to manage one level of sedation deeper than the level intended. Thus, cardiologists should be cognizant of the principles of managing deep sedation (depressed consciousness without easy arousal that may require assistance in maintaining airway patency or spontaneous ventilation).

A full review of procedural sedation is beyond the scope of this document, but practice guidelines for sedation and analgesia by nonanesthesiologists, along with The Joint Commission standards, provides a reasonable framework. These guidelines outline several general principles (558, 559). Before the procedure the patient should be assessed for predictors of difficult

ID: kandasamy.d | Black Lining: [ON] | Time: 12:18 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

intubation or a history of prior difficult intubation. The patient should be monitored by someone dedicated to observing the level and effects of sedation. Level of consciousness, respiratory rate, blood pressure, cardiac rhythm, and oxygen saturation by pulse oximetry should be monitored. Available equipment should include a high-flow oxygen source, suction, airway management equipment, a defibrillator, resuscitation drugs, and reversal agents appropriate for the drugs being used. A free-flowing IV line should be established. Supplemental oxygen is usually administered, even in the absence of preexisting hypoxia, to provide a margin of safety.

Agents used for sedation are best given in incremental doses, allowing adequate time for the development and assessment of peak effect. The most commonly used agents are listed in Appendix 4F.

5.7.2. Oral Antiplatelet Therapy: Recommendations

CLASS I

1. Patients already taking daily aspirin therapy should take 81 mg to 325 mg before PCI (301–304). *(Level of Evidence: B)*
2. Patients not on aspirin therapy should be given non-enteric aspirin 325 mg before PCI (301, 303, 304). *(Level of Evidence: B)*
3. After PCI, use of aspirin should be continued indefinitely (560–563). *(Level of Evidence: A)*
4. A loading dose of a $P2Y_{12}$ receptor inhibitor should be given to patients undergoing PCI with stenting (564–568) *(Level of Evidence: A)*. Options include
   a. Clopidogrel 600 mg (ACS and non-ACS patients) (564–566) *(Level of Evidence: B)*
   b. Prasugrel 60 mg (ACS patients) (567) *(Level of Evidence: B)*
   c. Ticagrelor 180 mg (ACS patients) (568) *(Level of Evidence: B)*
5. The loading dose of clopidogrel for patients undergoing PCI after fibrinolytic therapy should be 300 mg within 24 hours and 600 mg more than 24 hours after receiving fibrinolytic therapy (565, 569). *(Level of Evidence: C)*
6. Patients should be counseled on the need for and risks of DAPT before placement of intracoronary stents, especially DES, and alternative therapies should be pursued if patients are unwilling or unable to comply with the recommended duration of DAPT (208). *(Level of Evidence: C)*
7. The duration of $P2Y_{12}$ inhibitor therapy after stent implantation should generally be as follows:
   a. In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ inhibitor therapy should be given for at least 12 months. Options include clopidogrel 75 mg daily (570), prasugrel 10 mg daily (567), and ticagrelor 90 mg twice daily (568). *(Level of Evidence: B)*
   b. In patients receiving DES for a non-ACS indication, clopidogrel 75 mg daily should be given for at least 12 months if patients are not at high risk of bleeding (208, 212, 571). *(Level of Evidence: B)*
   c. In patients receiving BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks) (208, 572). *(Level of Evidence: B)*

CLASS IIa

1. After PCI, it is reasonable to use aspirin 81 mg per day in preference to higher maintenance doses (302, 573–576). *(Level of Evidence: B)*
2. If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of $P2Y_{12}$ inhibitor therapy after stent implantation, earlier discontinuation (e.g., <12 months) of $P2Y_{12}$ inhibitor therapy is reasonable. *(Level of Evidence: C)*

CLASS IIb

1. Continuation of DAPT beyond 12 months may be considered in patients undergoing DES implantation (567, 568). *(Level of Evidence: C)*

CLASS III: HARM

1. Prasugrel should not be administered to patients with a prior history of stroke or transient ischemic attack (567). *(Level of Evidence: B)*

Aspirin reduces the frequency of ischemic complications after PCI. Although the minimum effective aspirin dosage in the setting of PCI has not been established, aspirin 325 mg given at least 2 hours, and preferably 24 hours, before PCI is recommended (302, 303), after which aspirin 81 mg daily should be continued indefinitely.

Several investigations have explored various loading doses of clopidogrel before or during PCI. Compared with a 300-mg loading dose, doses of either 600 mg or 900 mg achieve greater degrees of platelet inhibition with fewer low responders (577). A meta-analysis of 7 studies that included 25,383 patients undergoing PCI demonstrated that intensified loading of clopidogrel with 600 mg reduces the rate of MACE without an increase in major bleeding compared with 300 mg (578). Another study suggested that a 600-mg loading dose of clopidogrel is associated with improvements in procedural angiographic endpoints and 1-year clinical outcomes in patients with STEMI who undergo

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 37

primary PCI compared with a 300-mg dose (579). There is no benefit with increasing the loading dose to 900 mg compared with 600 mg (577). Clopidogrel 75 mg daily should be given for a minimum of 4 weeks after balloon angioplasty or BMS implantation (a minimum of 2 weeks if increased bleeding risk is present) (580) and for at least 12 months after DES implantation (unless the risk of bleeding outweighs the anticipated benefit). Patients should be counseled on the need for and risks of DAPT before stent implantation, especially DES implantation, and alternative therapies pursued (BMS or balloon angioplasty) if they are unwilling or unable to comply with the recommended duration of DAPT.

The efficacy of clopidogrel pretreatment remains controversial. Although some studies have suggested that pretreatment with clopidogrel is associated with decreased platelet aggregation and a significantly lower incidence of periprocedural MI after elective PCI, others have suggested no benefit to pretreatment compared with administration of the drug in the catheterization laboratory (572, 581, 582).

When prasugrel was compared with clopidogrel in patients with ACS in TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis In Myocardial Infarction), prasugrel was associated with a significant 2.2% reduction in absolute risk and a 19% reduction in relative risk in the composite endpoint of cardiovascular death, nonfatal MI, or nonfatal stroke, and a significant increase in the rate of TIMI major hemorrhage (1.8% versus 2.4%) (567). Prasugrel is contraindicated in patients with a history of transient ischemic attack or stroke. Patients weighing <60 kg have an increased risk of bleeding on the 10 mg daily maintenance dose. The package insert suggests that consideration should be given to lowering the maintenance dose to 5 mg daily, although the effectiveness and safety of the 5-mg dose has not been studied. Prasugrel is not recommended for patients >75 years of age because of the increased risk of fatal and intracranial bleeding and lack of benefit, except in patients with diabetes or a history of prior MI. Prasugrel should not be started in patients likely to undergo urgent CABG. Prasugrel has not been studied in elective PCI, and thus no recommendation can be made regarding its use in this clinical setting.

Ticagrelor reversibly binds the $P2Y_{12}$ receptor. Unlike clopidogrel or prasugrel, ticagrelor is not a thienopyridine. It also does not require metabolic conversion to an active metabolite. Compared with clopidogrel in patients with ACS in the PLATO (Platelet Inhibition and Patient Outcomes) trial, ticagrelor was associated with a significant 1.9% reduction in absolute risk and a 16% reduction in relative risk in the primary composite endpoint of vascular death, nonfatal MI, or nonfatal stroke (568). Importantly, a significant reduction in vascular mortality and all-cause mortality was observed. Although CABG-related bleeding was not significantly increased with ticagrelor compared with clopidogrel, a significantly greater incidence of major bleeding was observed in patients not undergoing CABG. Ticagrelor was associated with higher rates of transient dyspnea and bradycardia compared with clopidogrel, although only a very small percentage of patients discontinued the study drug because of dyspnea. Based on post hoc analysis of the PLATO study, specifically the results in the U.S. patient cohort, a black box warning states that maintenance doses of aspirin above 100 mg reduce the effectiveness of ticagrelor and should be avoided. After any initial dose, ticagrelor should be used with aspirin 75 mg to 100 mg per day (583). Given the twice-daily dosing and reversible nature of the drug, patient compliance may be a particularly important issue to consider and emphasize. Ticagrelor has not been studied in elective PCI or in patients who received fibrinolytic therapy; thus, no recommendations about its use in these clinical settings can be made.

5.7.3. IV Antiplatelet Therapy: Recommendations STEMI

CLASS IIa

1. In patients undergoing primary PCI treated with UFH, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban), whether or not patients were pretreated with clopidogrel (584–590). *(For GP IIb/IIIa inhibitor administration in patients not pretreated with clopidogrel, Level of Evidence: A; for GP IIb/IIIa inhibitor administration in patients pretreated with clopidogrel, Level of Evidence: C)*

CLASS IIb

1. In patients undergoing primary PCI with abciximab, it may be reasonable to administer intracoronary abciximab (589, 591–604). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. Routine precatheterization laboratory (e.g., ambulance or emergency department) administration of GP IIb/IIIa inhibitors as part of an upstream strategy for patients with STEMI undergoing PCI is not beneficial (605–612). *(Level of Evidence: B)*

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

UA/NSTEMI

CLASS I

1. In UA/NSTEMI patients with high-risk features (e.g., elevated tro-ponin level) not treated with bivalirudin and not adequately pre-treated with clopidogrel, it is useful at the time of PCI to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) in patients treated with UFH (613–618). *(Level of Evidence: A)*

CLASS IIa

1. In UA/NSTEMI patients with high-risk features (e.g., elevated troponin level) treated with UFH and adequately pretreated with clopidogrel, it is reasonable at the time of PCI to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) (616, 619). *(Level of Evidence: B)*

SIHD

CLASS IIa

1. In patients undergoing elective PCI treated with UFH and not pretreated with clopidogrel, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) (619–621). *(Level of Evidence: B)*

CLASS IIb

1. In patients undergoing elective PCI with stent implantation treated with UFH and adequately pretreated with clopidogrel, it might be reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-bolus dose tirofiban) (619, 622–624). *(Level of Evidence: B)*

See Online Data Supplement 24 for additional data regarding IV antiplatelet therapy.

In the era before DAPT, trials of adequately dosed GP IIb/IIIa inhibitors in patients undergoing balloon angioplasty and coronary stent implantation demonstrated a reduction in the incidence of composite ischemic events with GP IIb/IIIa treatment, primarily through a reduction of enzymatically defined MI (613, 615, 618, 620, 621). Earlier RCTs of GP IIb/IIIa inhibitors were generally conducted in patients treated with UFH. In some trials, use of GP IIb/IIIa inhibitors are associated with some increased bleeding risk, and trials of these agents have generally excluded patients at high risk of bleeding (e.g., coagulopathy) (584, 587–589, 613–618, 620–626). Thus, recommendations about use of GP IIb/IIIa inhibitors are best construed as applying to those patients not at high risk of bleeding complications. Abciximab, double-bolus eptifibatide (180 mcg/kg bolus followed 10 minutes later by a second 180 mcg/kg bolus), and high-bolus dose tirofiban (25 mcg/kg) all result in a high degree of platelet inhibition (627–629), have been demonstrated to reduce ischemic complications in patients undergoing PCI (608, 609, 613, 615, 618–621), and appear to lead to comparable angiographic and clinical outcomes (630, 631).

Trials of GP IIb/IIIa inhibitors in the setting of STEMI and primary PCI were conducted in the era before routine stenting and DAPT. The results of these and more recent trials, as well as several meta-analyses, have yielded mixed results (584–590). Therefore, it is reasonable to administer GP IIb/IIIa inhibitors in patients with STEMI undergoing PCI, although these agents cannot be definitively recommended as routine therapy. These agents might provide more benefit in selective use, such as in patients with large anterior MI and/or large thrombus burden. Trials of precatheterization laboratory (e.g., ambulance or emergency room) administered GP IIb/IIIa inhibitors in patients with STEMI undergoing PCI, with or without fibrinolytic therapy, have generally shown no clinical benefit, and GP IIb/IIIa inhibitor use in this setting may be associated with an increased risk of bleeding (605–610, 612). Studies of intracoronary GP IIb/IIIa inhibitor administration (predominantly using abciximab) consist of several small RCTs, retrospective analyses, retrospective and prospective registries, cohort analyses, and case reports. Although most of these published studies have reported some benefit of intracoronary administration in terms of acute angiographic parameters, infarct size, left ventricle myocardial salvage, and composite clinical endpoints, several other studies have not detected any benefit with intracoronary administration (589, 591–604).

Trials of GP IIb/IIIa inhibitors in patients with UA/NSTEMI undergoing PCI demonstrated reduced ischemic outcomes, particularly in those with high-risk features such as positive biomarkers. Most trials were conducted in a prior PCI era and without $P2Y_{12}$ inhibitor pretreatment (613, 615, 618, 632, 633), although several trials have also demonstrated benefit in patients with high-risk features pretreated with clopidogrel (616, 619). In most older studies of stable patients undergoing balloon angioplasty or coronary stenting, treatment with GP IIb/IIIa inhibitors resulted in a reduction of composite ischemic events, primarily enzymatically defined MI (613–618, 620, 621, 634, 635). More contemporary trials of patients pretreated with a thienopyridine have not demonstrated any benefit with GP IIb/IIIa inhibitor therapy in patients with stable symptoms undergoing elective PCI (619, 622–624).

TABLE 12. Dosing of Parenteral Anticoagulants During PCI

Drug	Patient Has Received Prior Anticoagulant Therapy	Patient Has Not Received Prior Anticoagulant Therapy
UFH	• IV GPI planned: additional UFH as needed (e.g., 2,000 to 5,000 U) to achieve an ACT of 200 to 250 s • No IV GPI planned: additional UFH as needed (e.g., 2,000 to 5,000 U) to achieve an ACT of 250 to 300 s for HemoTec, 300 to 350 s for Hemochron	• IV GPI planned: 50 to 70 U/kg bolus to achieve an ACT of 200 to 250 s • No IV GPI planned: 70 to 100 U/kg bolus to achieve target ACT of 250 to 300 s for HemoTec, 300 to 350 s for Hemochron
Enoxaparin	• For prior treatment with enoxaparin, if the last SC dose was administered 8 to 12 h earlier or if only 1 SC dose of enoxaparin has been administered, an IV dose of 0.3 mg/kg of enoxaparin should be given. • If the last SC dose was administered within the prior 8 h, no additional enoxaparin should be given.	0.5 to 0.75 mg/kg IV bolus
Bivalirudin	For patients who have received UFH, wait 30 min, then give 0.75 mg/kg IV bolus, then 1.75 mg/kg per h IV infusion.	0.75 mg/kg bolus, 1.75 mg/kg per h IV infusion
Fondaparinux	For prior treatment with fondaparinux, administer additional IV treatment with an anticoagulant possessing anti-IIa activity, taking into account whether GPI receptor antagonists have been administered.	N/A
Argatroban	200 mcg/kg IV bolus, then 15 mcg/kg per min IV infusion	350 mcg/kg bolus, then 15 mcg/kg per min IV infusion

ACT indicates activated clotting time; IV, intravenous; GPI, glycoprotein inhibitor; N/A, not applicable; PCI, percutaneous coronary intervention; SC, subcutaneous; and UFH, unfractionated heparin.

5.7.4. Anticoagulant Therapy

5.7.4.1. USE OF PARENTERAL ANTICOAGULANTS DURING PCI: RECOMMENDATION

CLASS I

1. An anticoagulant should be administered to patients undergoing PCI. *(Level of Evidence: C)*

Anticoagulant therapy prevents thrombus formation at the site of arterial injury, on the coronary guidewire, and in the catheters used for PCI (8). With rare exceptions (636), all PCI studies have used some form of anticoagulant. It is the consensus of the writing committee that PCI be performed with the use of some form of anticoagulant therapy. Suggested dosing regimens of parenteral agents used in PCI are given in Table 12. Recommendations for antiplatelet and antithrombin pharmacotherapy in PCI are given in Table 13.

5.7.4.2. UFH: RECOMMENDATION

CLASS I

1. Administration of IV UFH is useful in patients undergoing PCI. *(Level of Evidence: C)*

As the only anticoagulant available for PCI for many years, UFH became the standard of care by default (8). The dose of UFH for PCI has been based on empiricism and experience from RCTs. Suggested UFH dosing regimens are given in Table 12. When UFH is used during PCI, most cardiologists assess the degree of anticoagulation by measuring the activated clotting time. Although measurements are useful to show that an anti-IIa anticoagulant has been given, the value of the activated clotting time in current practice has been questioned. Although studies in the balloon angioplasty era did demonstrate a relationship between activated clotting time levels and ischemic complications (653–655), more recent analyses from the coronary stent era have not found a clear relationship between activated clotting time and outcomes (349, 656, 657). There may, however, be a modest relation between bleeding and activated clotting time levels (349, 657). In addition, not only are there differences between activated clotting time levels measured by Hemochron and HemoTec devices, but both devices have less than optimal precision (658). Thus, although traditional target activated clotting time levels are included in this document, the utility of measured activated clotting time levels in current practice should be considered uncertain.

Most cardiologists remove femoral sheaths when the activated clotting time falls to <150 to 180 seconds or when the activated partial thromboplastin time falls to <50 seconds. Full-dose anticoagulation is no longer used after successful PCI procedures. Almost all large clinical trials have enrolled patients who underwent transfemoral PCI, but recent small studies assessing the transradial approach have used similar doses of UFH (659) and similar activated clotting time target levels (660).

5.7.4.3. ENOXAPARIN: RECOMMENDATIONS

CLASS I

1. An additional dose of 0.3 mg/kg IV enoxaparin should be administered at the time of PCI to patients who have received fewer than 2 therapeutic

	SIHD: IIb	B	(619, 622–624)	
Antithrombin agents				
UFH	I	C	N/A	• Dosing based on whether or not GPI was administered.
Bivalirudin	I	B	(625, 637–645)	• Lower bleeding rates associated with bivalirudin are mitigated when used concomitantly with a GPI.
Enoxaparin	IIb	B	(646–650)	• Recommendations apply to administration of IV enoxaparin at the time of PCI for those who have not received prior antithrombin therapy or who have received "upstream" SC enoxaparin therapy for UA/NSTEMI. • An additional dose of 0.3 mg/kg IV enoxaparin should be administered at the time of PCI to patients who have received <2 therapeutic SC doses (e.g., 1 mg/kg) or received the last SC enoxaparin dose 8 to 12 h before PCI: ***Class I; LOE: B.*** • Patients treated with SC enoxaparin within 12 h of PCI should not receive additional treatment with UFH during PCI ("stacking"): ***Class III: Harm; LOE: B.***
Anti-Xa inhibitors				
Fondaparinux	III: Harm	C	(651, 652)	• PCI should not be performed with fondaparinux as the sole antithrombin agent in patients treated with upstream fondaparinux. An additional anticoagulant with anti-IIa activity should be administered.

ACT indicates activated clotting time; COR, class of recommendation; CVA, cerebrovascular accident; FDA, U.S. Food and Drug Administration; GP, glycoprotein; GPI, glycoprotein IIb/IIIa inhibitor; IC, intracoronary; IV, intravenous; LOE, level of evidence; MI, myocardial infarction; N/A, not applicable; PCI, percutaneous coronary intervention; SC, subcutaneous; SIHD, stable ischemic heart disease; STEMI, ST-elevation myocardial infarction; TIA, transient ischemic attack; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; and UFH, unfractionated heparin.

subcutaneous doses (e.g., 1 mg/kg) or received the last subcutaneous enoxaparin dose 8 to 12 hours before PCI (649, 661–664). *(Level of Evidence: B)*

CLASS IIb

1. Performance of PCI with enoxaparin may be reasonable in patients either treated with "upstream" subcutaneous enoxaparin for UA/ NSTEMI or who have not received prior antithrombin therapy and are administered IV enoxaparin at the time of PCI (646–650). *(Level of Evidence: B)*

CLASS III: HARM

1. UFH should not be given to patients already receiving therapeutic subcutaneous enoxaparin (649, 665). *(Level of Evidence: B)*

Trials of enoxaparin relevant to PCI include both studies in which patients with UA/NSTEMI were started on upstream subcutaneous enoxaparin therapy that was continued up to the time of PCI and trials in which patients who had received no prior antithrombin therapy were treated with IV enoxaparin at the time of PCI (646–650, 661–663, 666). In the SYNERGY

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

(Superior Yield of the New strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial, there was an increased incidence of bleeding in those treated with upstream enoxaparin, later attributed at least in part to the fact that some patients being treated with enoxaparin were also administered UFH at the time of PCI (so-called "stacking") (649, 665). Almost all patients undergoing elective PCI who are administered enoxaparin (0.5 mg/kg IV) will have a peak anti-Xa level > 0.5 IU/mL (647). Most clinical studies have used a regimen of 0.5 to 0.75 mg IV (667). Several studies have used this regimen in elective patients and those with STEMI (646). Patients who have received multiple doses of subcutaneously administered enoxaparin who undergo PCI within 8 hours of the last subcutaneous dose generally have adequate degrees ofanticoagulation to undergo PCI, but the degree of anticoagulation may diminish in the 8- to 12-hour period after the last subcutaneous dose. In such patients, as well as in patients who have received only 1 subcutaneous dose of enoxaparin, the addition of enoxaparin (0.3 mg/kg IV) at the time of PCI provides an additional degree of anticoagulation and has become standard practice (648, 661–664). Patients who undergo PCI >12 hours after the last subcutaneous dose are usually treated with full-dose de novo anticoagulation using an established regimen (e.g., full-dose UFH or bivalirudin).

5.7.4.4. BIVALIRUDIN AND ARGATROBAN: RECOMMENDATIONS

CLASS I

1. For patients undergoing PCI, bivalirudin is useful as an anticoagulant with or without prior treatment with UFH (625, 637–645). *(Level of Evidence: B)*
2. For patients with heparin-induced thrombocytopenia, it is recommended that bivalirudin or argatroban be used to replace UFH (668, 669). *(Level of Evidence: B)*

Bivalirudin is being increasingly used in clinical practice (670) as evidence emerges from clinical trials across the spectrum of CAD (638–644). In individual trials and meta-analyses, the use of bivalirudin has been associated with reduced bleeding compared with UFH plus a GP IIb/IIIa inhibitor, although concerns about ischemic events have emerged in individual studies (625, 637–645). Longer-term follow-up of the major bivalirudin trials, however, suggests that small or nominal increases in ischemic events have not translated into long-term consequences and that treatment at or before the time of PCI with clopidogrel may mitigate any increased early ischemic risk (637–645). Thus, a treatment strategy of bivalirudin compared with heparin (or enoxaparin) plus GP IIb/IIIa inhibitor appears to lower the risk of bleeding complications. The lower bleeding rates associated with bivalirudin (compared with UFH plus a GP IIb/IIIa inhibitor) are mitigated when used concomitantly with a GP IIb/IIIa inhibitor (639). A strategy of use of provisional GP IIb/IIIa inhibitor in patients treated with bivalirudin is widely accepted (639, 643, 644).

In patients with heparin-induced thrombocytopenia (671, 672), a direct-thrombin inhibitor (argatroban) has been approved as an alternative parenteral anticoagulant to be used during PCI (668). The use of bivalirudin for heparin-induced thrombocytopenia has been reported as well (669).

5.7.4.5. FONDAPARINUX: RECOMMENDATION

CLASS III: HARM

1. Fondaparinux should not be used as the sole anticoagulant to support PCI. An additional anticoagulant with anti-IIa activity should be administered because of the risk of catheter thrombosis (651, 652). *(Level of Evidence: C)*

Fondaparinux, a pentasaccharide, is an indirect factor Xa inhibitor but has no effect on thrombin. On the basis of reports of catheter thrombosis when fondaparinux is used alone during primary PCI (651, 652), the writing committee recommends that an anticoagulant with anti-IIa activity be used in patients undergoing PCI (651, 652). One study suggested that clinical outcomes were better when fondaparinux was replaced during PCI by a standard dose of UFH (85 U/kg, 60 U/kg with GP IIb/IIIa inhibitors) rather than by a low dose (50 U/kg) (673).

5.7.5. No-Reflow Pharmacological Therapies: Recommendation

CLASS IIa

1. Administration of an intracoronary vasodilator (adenosine, calcium channel blocker, or nitroprusside) is reasonable to treat PCI-related no-reflow that occurs during primary or elective PCI (674–689). *(Level of Evidence: B)*

See Online Data Supplement 25 for additional data regarding no-reflow therapies.

No-reflow is a broad term used to describe 2 distinct entities. The first is "interventional no-reflow" attributed to vasospasm and downstream embolization of debris dislodged during PCI, usually in the setting of atherectomy, thrombus, or degenerated SVGs. The second entity is suboptimal reperfusion of an infarct artery, attributed to endothelial injury in addition to embolization and vasospasm. Angiographic no-reflow is the most obvious sequela of the same

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

pathophysiology that produces abnormal TIMI frame counts and TIMI blush scores, so these measures are often used interchangeably. The principal clinical sequela of no-reflow is myonecrosis. Efforts to prevent no-reflow overlap with strategies to reduce MI size and prevent periprocedural MI.

In the setting of MI, several drugs have been shown to reduce the incidence of no-reflow. Evidence for a beneficial effect on no-reflow exists for abciximab, adenosine, nicorandil, and nitroprusside (674, 675, 680, 682, 683, 685, 687, 688, 690). However, their adoption into clinical practice has depended on their effect on hard clinical endpoints such as infarct size and mortality. These benefits, and consequentially the use of these agents, have been limited.

For interventional no-reflow, several therapies have proven effective after no-reflow has started. These include adenosine, calcium channel blockers, and nitroprusside (676, 678, 679, 681, 684, 686, 689, 691). There are fewer data to support the use of epinephrine (692). No-reflow after rotational atherectomy was less common with nicorandil compared with verapamil infusions in 3 studies (693–695), and an infusion of nicorandil/adenosine during rotational atherectomy prevented no-reflow in 98% of patients (677). Trials of pre-PCI intracoronary verapamil, nicardipine, and adenosine have reported them to be safe but have not demonstrated reductions in post-PCI no-reflow (696–698). Mechanical devices to prevent interventional and myocardial infarct reperfusion no-reflow are also covered in Section 5.5.5.

5.8. PCI in Specific Anatomic Situations

5.8.1. CTOs: Recommendation

CLASS IIa

1. PCI of a CTO in patients with appropriate clinical indications and suitable anatomy is reasonable when performed by operators with appropriate expertise (699–703). *(Level of Evidence: B)*

See Online Data Supplements 26 to 28 for additional data regarding CTOs.

Approximately one third of patients with suspected CAD who undergo coronary angiography have $\geq$ 1 CTO (defined as occlusion of a duration >3 months) (704). Although stress-induced ischemia can be elicited in the majority of patients with CTO despite the presence of collaterals (706, 707), only 8% to 15% of these patients undergo PCI (708, 709). The disparity between the frequency of CTOs and percutaneous treatment underscores not only the technical and procedural complexities of this lesion subtype but also the clinical uncertainties regarding which patients benefit from CTO revascularization. Studies suggest that patients who undergo successful, rather than failed, recanalization of CTOs fare better in terms of symptom status and need for CABG (699), as well as LV function (710). However, the impact of successful CTO recanalization on long-term survival remains unsettled (701, 711, 712). The decision to try PCI for a CTO (versus continued medical therapy or surgical revascularization) requires an individualized risk-benefit analysis encompassing clinical, angiographic, and technical considerations. Consultation with a cardiothoracic surgeon and use of the Heart Team approach in cases of CTO in which a large territory is subtended and/or multivessel CAD is present are frequently done.

From a technical perspective, successful recanalization of CTOs has steadily increased over the years because of adoption of dedicated wires, novel techniques, and increased operator experience (702). In patients who undergo successful CTO recanalization, use of DES significantly reduces the need for repeated target-vessel revascularization, compared with BMS and balloon angioplasty, without compromising safety (703, 713–719).

5.8.2. SVGs: Recommendations

CLASS I

1. EPDs should be used during SVG PCI when technically feasible (532–535). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. Platelet GP IIb/IIIa inhibitors are not beneficial as adjunctive therapy during SVG PCI (212, 571, 720, 721). *(Level of Evidence: B)*

CLASS III: HARM

1. PCI is not recommended for chronic SVG occlusions (722–724). *(Level of Evidence: C)*

See Online Data Supplement 29 for additional data regarding SVG.

Adverse cardiac event rates are doubled after SVG PCI compared with native-artery PCI (536). A distal balloon occlusion EPD decreased the 30-day composite outcome of death, MI, emergency CABG, or target-lesion revascularization (9.6% versus 16.5%) in the only RCT comparing embolic protection with no embolic protection (532). Subsequent noninferiority comparisons have demonstrated similar benefit with proximal occlusion and distal filter EPDs, with benefit limited to reduction in periprocedural MI (534, 535). PCI in chronic SVG occlusion is associated with low success rates, high complication rates, and poor long-term patency rates (722, 723). Restenosis and target-vessel revascularization rates are lower with DES compared with BMS, although mortality and stent thrombosis rates are similar (725). The use of covered stents is

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 43

limited to the treatment of the uncommon complication of SVG perforation. Balloon angioplasty for distal SVG anastomotic stenoses has low restenosis rates (724), so stenting is commonly reserved at this location for suboptimal balloon angioplasty results or restenosis. Routine GP IIb/IIIa inhibitor therapy has not proven beneficial in SVG PCI (720). Fibrinolytic therapy is no longer used for thrombus-containing lesions, but rheolytic or manual aspiration thrombectomy is sometimes employed.

5.8.3. Bifurcation Lesions: Recommendations

CLASS I

1. Provisional side-branch stenting should be the initial approach in patients with bifurcation lesions when the side branch is not large and has only mild or moderate focal disease at the ostium (726–729). *(Level of Evidence: A)*

CLASS IIa

1. It is reasonable to use elective double stenting in patients with complex bifurcation morphology involving a large side branch where the risk of side-branch occlusion is high and the likelihood of successful side-branch reaccess is low (730–733). *(Level of Evidence: B)*

Side-branch occlusion or severe stenosis after stenting the main artery in coronary bifurcation PCI occurs in 8% to 80% of unselected patients (732, 734). The frequency of side-branch occlusion is related to complex bifurcation morphology (severe and/or long side-branch ostial stenosis, large plaque burden in the side-branch ostium, and/or unfavorable side-branch angulation) (732, 735, 736). Side-branch occlusion after PCI is associated with Q-wave and non-Q-wave MI (734, 735). Therefore, preservation of physiologic flow in the side branch after PCI is important (736). There are 2 bifurcation PCI strategies: provisional stenting (stenting the main vessel with additional balloon angioplasty or stenting of the side branch only in the case of an unsatisfactory result) and elective double stenting of the main vessel and the side branch. When there is an unsatisfactory result in the side branch from the provisional stent in the main branch, sometimes balloon angioplasty alone in the side branch will improve the result and stenting the side branch is not necessary. Some experts have suggested that using the side-branch balloon alone will distort the main branch stent and thus this always needs to be a kissing balloon inflation.

In patients with low-risk bifurcation lesions (minimal or moderate ostial side-branch disease [<50% diameter stenosis] of focal length [5 to 6 mm]), provisional stenting yields similar clinical outcome to elective double stenting, with lower incidence of periprocedural biomarker elevation (726–729). Conversely, in patients with high-risk bifurcations, elective double stenting is associated with a trend toward higher angiographic success rates, lower in-hospital MACE, and better long-term patency of the side branch compared with provisional stenting (193). Culotte, Crush, and T-stent techniques have been studied in RCTs (726–729, 737). Use of DES yields better outcomes than BMS (738), and sirolimus-eluting stents yield better outcomes than paclitaxel-eluting stents (739–742). Clinical evidence supports the use of final kissing balloon inflation after elective double stenting (743).

5.8.4. Aorto-Ostial Stenoses: Recommendations

CLASS IIa

1. IVUS is reasonable for the assessment of angiographically indeterminant left main CAD (744, 745). *(Level of Evidence: B)*
2. Use of DES is reasonable when PCI is indicated in patients with an aorto-ostial stenosis (746, 747). *(Level of Evidence: B)*

Aorto-ostial stenoses of native coronary arteries (left main coronary artery and right coronary artery) are most commonly caused by atherosclerosis, but they can also occur in patients with congenital malformations, radiation exposure, vasculitides, and aortic valve replacement. The angiographic diagnosis of aorto-ostial disease is not always straightforward, especially in the ostial left main coronary artery, where eccentricity and angulation can be mistaken for stenosis (490, 748). Aorto-ostial disease can be evaluated with IVUS (744, 745); FFR (with IV adenosine) has also been used (484, 749). The treatment of aorto-ostial stenoses with balloon angioplasty has been associated with lower procedural success rates, more frequent in-hospital complications, and a greater likelihood of late restenosis (750). Although atherectomy devices (directional atherectomy, rotational atherectomy, and excimer laser angioplasty) have improved acute angiographic results over balloon angioplasty, restenosis has remained a limitation (751). In patients with aorto-ostial stenoses undergoing PCI, use of DES has been shown to reduce restenosis compared with BMS (176, 746, 752).

5.8.5. Calcified Lesions: Recommendation

CLASS IIa

1. Rotational atherectomy is reasonable for fibrotic or heavily calcified lesions that might not be crossed by a balloon catheter or adequately dilated before stent implantation (514, 515, 520). *(Level of Evidence: C)*

The presence of coronary calcification is a marker for significant CAD and increased long-term mortality

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

(753). Calcified coronary lesions are not a homogenous entity, and their response to PCI varies according to severity of calcification. Severely calcified lesions respond poorly to balloon angioplasty (230, 754), and when stents are implanted in such lesions, an incomplete and asymmetrical stent expansion occurs in the majority of cases (755). Attempts to remedy the underexpanded stents with aggressive high-pressure balloon dilatation may result in coronary artery rupture (756). All the published prospective RCTs that evaluated the various catheter-based coronary interventional devices excluded patients with severely calcified lesions. Therefore, the evidence base for best PCI practices in patients with severely calcified lesions comes from nonrandomized single-arm studies. Among the various adjunct devices that are used to facilitate PCI in severely calcified lesions, only rotational atherectomy has been shown to have potential utility (514, 757). Although rotational atherectomy increases the chances of angiographic success in severely calcified lesions, its use as a stand-alone device has not led to a reduction in restenosis (520, 521, 758). Several retrospective studies have shown that in patients with severely calcified lesions, the use of rotational atherectomy before implantation of BMS (514)or DES(515)is safe. Intermediate-term patency is more favorable with DES than BMS (759).

5.9. PCI in Specific Patient Populations

Several specific patient subsets with higher risks for PCI, and at times higher absolute clinical benefit, have traditionally been underrepresented in RCTs and are described below.

5.9.1. Elderly. The elderly constitute a growing proportion of patients considered for PCI (760). In 1 series examining trends over a 25-year period, the proportion of patients undergoing PCI who were 75 to 84 years of age doubled, and those >85 years of age increased 5-fold (761). Age is one of the strongest predictors of mortality after PCI (762), and elderly patients present with a substantially higher clinical risk profile (760). Nonetheless, the angiographic success rates and clinical benefits of PCI in elderly patients are similar to younger patients (763). In fact, the absolute benefit is typically greater because of higher absolute risk of adverse outcomes in these patients (764). However, increased risks of complications such as major bleeding and stroke mandate careful consideration of the benefits and risks of PCI in elderly patients (373).

5.9.2. Diabetes. Patients with diabetes represent approximately one third of patients undergoing PCI in the United States. Restenosis, which had been a major limitation of PCI, is significantly reduced in patients with diabetes treated with DES compared with BMS (471). However, there are no definitive data from RCTs supporting different clinical outcomes for different types of DES (765), with a recent meta-analysis of 35 RCTs involving 3,852 patients with diabetes unable to find major differences between patients receiving sirolimus-eluting stents or paclitaxel-eluting stents (472). Numerous analyses and clinical studies have evaluated how the presence of diabetes may impact the clinical outcome of patients undergoing PCI and decisions about PCI or CABG (14, 116, 163, 164, 186). These studies and the approach to revascularization decisions in diabetes are addressed in Section 4.

Diabetes is an important risk factor for the development of contrast-induced AKI. Strategies to reduce the risk of contrast-induced AKI in patients with diabetes are discussed in Section 4.4.

5.9.3. Women. Cardiovascular disease is the leading cause of death in women in the United States and Europe (766), and an estimated 35% of PCIs in the United States are performed in women (767, 768). Women undergoing PCI usually have more risk factors (including hypertension, advanced age, elevated cholesterol, and more significant and diffuse CAD) compared with men (769). Women with STEMI are also less likely to receive early medical treatments and experience longer delays to reperfusion therapy (770, 771). In subgroup analyses of clinical trials, use of DES appears to be similarly efficacious in women and men (772).

5.9.4. CKD: Recommendation

CLASS I

1. In patients undergoing PCI, the glomerular filtration rate should be estimated and the dosage of renally cleared medications should be adjusted (298–300). *(Level of Evidence: B)*

CKD is an independent risk factor for the development and progression of CAD (773, 774), and is also associated with worse prognosis after MI or PCI (369, 775). A glomerular filtration rate of <60 mL/min per 1.73 m^2 of body surface area should be considered abnormal. Patients with CKD undergoing PCI have a higher risk ofcomplications, including bleeding (776), AKI, and death (236, 777), but CKD is not a strong predictor of restenosis after BMS or DES (778). Strategies to reduce the risk of contrast-induced AKI in patients with CKD are discussed in Section 4.4. Platelet dysfunction and overdosing of antiplatelet and antithrombin drugs (350) in patients with CKD contribute to the increased risk of bleeding. The Cockcroft-Gault formula is commonly used as a surrogate marker for estimating creatinine clearance, which in turn estimates glomerular filtration rate (298, 299, 779, 780).

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.

J_ID: Z7V Customer A_ID: 2011_PCI_Guideline Cadmus Art: CCD23390 Date: 3-November-11 Stage: Page: 45

Medications that require dosage adjustments in patients with CKD include eptifibatide, tirofiban, bivalirudin, enoxaparin, and fondaparinux (781).

5.9.5. Cardiac Allografts. Cardiac allograft vasculopathy is a major cause of death in cardiac transplant recipients after their first year of survival (782). In general, revascularization for cardiac allograft vasculopathy with PCI is only palliative, with no evidence supporting benefit in regard to long-term survival or avoidance of retransplantation. The restenosis rate after PCI in patients with cardiac allograft vasculopathy is high, although stent implantation reduces early and midterm reste-nosis compared with balloon angioplasty. DES have been shown to have a tendency to lower restenosis rates compared with BMS (783, 784). Thus, many clinicians perform stenting with DES or BMS in cardiac transplant patients with discrete lesions who have an abnormal stress test or symptoms suggestive of myocardial ischemia.

5.10. Periprocedural MI Assessment: Recommendations

CLASS I

1. In patients who have signs or symptoms suggestive of MI during or after PCI or in asymptomatic patients with significant *persistent* angiographic complications (e.g., large side-branch occlusion, flow-limiting dissection, no-reflow phenomenon, or coronary thrombosis), creatinine kinase-MB and troponin I or T should be measured. *(Level of Evidence: C)*

CLASS IIb

1. Routine measurement of cardiac biomarkers (creatinine kinase-MB and/or troponin I or T) in all patients after PCI may be reasonable. *(Level of Evidence: C)*

Major events leading to ischemia or MI after PCI include acute closure, embolization and no-reflow, side-branch occlusion, and acute stent thrombosis. Issues surrounding the routine assessment of cardiac biomarkers after PCI are complex, especially given that the definition of PCI-related MI has evolved over the years and most events are asymptomatic. The most recent consensus definition of MI considers troponin elevations of 3 times the upper limit of normal as a PCI-related MI in patients with normal baseline levels; this is further classified as a type 4a MI (240). This definition is supported by studies with delayed-enhancement MRI confirming that there is irreversible injury in the myocardium associated with biomarker elevations and that the size of this injury correlates with the degree of elevation (785). Furthermore, a meta-analysis of 15 observational studies found that troponin elevations at any level were linked with worse in-hospital and long-term outcomes; elevations >3 times the upper limit of normal predicted even worse outcomes (242). Other observational data, however, have raised concerns about whether the relationship is causal (786, 787). A recent study found creatinine kinase-MB to correlate better with MRI-detected MI than troponin level (788). Definitions of PCI-related MI are being reevaluated by the Task Force for the Redefinition of Myocardial Infarction. Although there may be value for individual operators and hospitals to routinely measure cardiac biomarkers to track rates of PCI-related MI, at present there are not compelling data to recommend this for all PCI procedures.

5.11. Vascular Closure Devices: Recommendations

CLASS I

1. Patients considered for vascular closure devices should undergo a femoral angiogram to ensure their anatomic suitability for deployment. *(Level of Evidence: C)*

CLASS IIa

1. The use of vascular closure devices is reasonable for the purposes of achieving faster hemostasis and earlier ambulation compared with the use of manual compression (257, 789–791). *(Level of Evidence: B)*

CLASS III: NO BENEFIT

1. The routine use of vascular closure devices is not recommended for the purpose of decreasing vascular complications, including bleeding (256, 257, 789–792). *(Level of Evidence: B)*

See Online Data Supplement 30 for additional data regarding vascular closure devices.

Vascular (arteriotomy) closure devices have been extensively reviewed (790), most recently in a 2010 AHA scientific statement (257), which issued several formal recommendations. The results of 4 meta-analyses have found that vascular closure devices decrease time to hemostasis compared with manual compression but do not decrease vascular complications, bleeding complications, or the need for blood transfusions (256, 789, 791, 793). Future studies of vascular closure devices need to be randomized, include "high-risk" patients and "high-risk" anatomy, use blinded endpoint adjudication as much as possible, use well-defined and comprehensive complication endpoints, and be adequately powered to

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

detect clinically important endpoints, particularly bleeding and vascular complications.

6. POSTPROCEDURAL CONSIDERATIONS

Postprocedural considerations in patients undergoing PCI are discussed below and summarized in Table 14. Some recommendations and text regarding DAPT in Section 5.7.2 are intentionally repeated in this section for reader ease of use.

T14

6.1. Postprocedural Antiplatelet Therapy: Recommendations

CLASS I

1. After PCI, use of aspirin should be continued indefinitely (560–563). *(Level of Evidence: A)*
2. The duration of $P2Y_{12}$ inhibitor therapy after stent implantation should generally be as follows:
   a. In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ inhibitor therapy should be given for at least 12 months. Options include clopidogrel 75 mg daily (570), prasugrel 10 mg daily (567), and ticagrelor 90 mg twice daily (568). *(Level of Evidence: B)*
   b. In patients receiving DES for a non-ACS indication, clopidogrel 75 mg daily should be given for at least 12 months if the patient is not at high risk of bleeding (208, 212, 571). *(Level of Evidence: B)*
   c. In patients receiving BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks) (572). *(Level of Evidence: B)*
3. Patients should be counseled on the importance of compliance with DAPT and that therapy should not be discontinued before discussion with their cardiologist (208). *(Level of Evidence: C)*

CLASS IIa

1. After PCI, it is reasonable to use aspirin 81 mg per day in preference to higher maintenance doses (302, 573–576). *(Level of Evidence: B)*
2. If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of $P2Y_{12}$ inhibitor therapy after stent implantation, earlier discontinuation (e.g., <12 months) of $P2Y_{12}$ inhibitor therapy is reasonable. *(Level of Evidence: C)*

CLASS IIb

1. Continuation of clopidogrel, prasugrel, or ticagrelor beyond 12 months may be considered in patients undergoing placement of DES (567, 568). *(Level of Evidence: C)*

Continued treatment with the combination of aspirin and a $P2Y_{12}$ inhibitor antagonist after PCI appears to reduce MACE (570, 572). On the basis of RCT protocols, secondary prevention measures, and expert consensus opinion, aspirin 81 mg daily should be given indefinitely after PCI.

Likewise, $P2Y_{12}$ inhibitors should be given for a minimum of1 month after BMS (minimum 2 weeks for patients at significant increased risk of bleeding) (580) and for 12 months after DES and ideally in all patients who are not at high risk of bleeding.

The 2009 STEMI/PCI guidelines update (10) listed the recommendation "if the risk of morbidity because of bleeding outweighs the anticipated benefit afforded by thienopyridine therapy, earlier discontinuation *should be considered*" as a Class I recommendation, although the language used, in part, was consistent with a Class IIa recommendation. To clarify the intent ofthe recommendation, as well as to acknowledge the inherent difficulties in weighing bleeding and stent thrombosis risks, the recommendation is designated a Class IIa recommendation, using the phrase "earlier discontinuation *is reasonable*." Recommendations regarding $P2Y_12$ inhibitor discontinuation before elective or urgent CABG are provided in the "2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft Surgery" (824).

6.1.1. PPIs and Antiplatelet Therapy: Recommendations

CLASS I

1. PPIs should be used in patients with a history of prior gastrointestinal (GI) bleeding who require DAPT (794). *(Level of Evidence: C)*

CLASS IIa

1. Use of PPIs is reasonable in patients with an increased risk of GI bleeding (e.g., advanced age, concomitant use of warfarin, steroids, nonsteroidal anti-inflammatory drugs, *Helicobacter pylori* infection) who require DAPT (794). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Routine use of a PPI is not recommended for patients at low risk of GI bleeding, who have much less potential to benefit from prophylactic therapy (794). *(Level of Evidence: C)*

See Online Data Supplement 31 for additional data regarding the clopidogrel—PPI interaction.

PPIs are often prescribed prophylactically when clopi-dogrel is started to prevent GI complications such

as ulceration and bleeding due to DAPT (825). There is pharmacodynamic evidence that omeprazole interferes with clopidogrel metabolism (826, 827), but there is no clear evidence implicating other PPIs. However, even with omeprazole, there are no convincing data supporting an important clinical drug-drug interaction (826). The FDA communication about an ongoing safety review of clopidogrel advises that healthcare providers avoid the use of clopidogrel in patients with impaired *CYP2C19* function due to known genetic variation or drugs that inhibit *CYP2C19* activity. The FDA notes that there is no evidence that other drugs that reduce stomach acid, such as histamine-2 receptor antagonists (except cimetidine) or antacids, interfere with clopidogrel responsiveness. The COGENT (Clopidogrel and the Optimization of Gastrointestinal Events) trial randomized patients with DAPT to clopidogrel and omeprazole or clopidogrel and placebo, and while there was no difference in cardiovascular events between the 2 groups, GI events were halved in those randomized to omeprazole (828). It is reasonable to carefully evaluate the indication for PPI therapy in patients treated with clopidogrel, based on the presence or absence of the risk factors discussed above (794). The need for GI protection increases with the number of risk factors for bleeding. Prior upper GI bleeding is the strongest and most consistent risk factor for GI bleeding on antiplatelet therapy. Patients with ACS and prior upper GI bleeding are at substantial cardiovascular risk, so DAPT with concomitant use of a PPI may provide the optimal balance of risk and benefit. It should be noted that PPIs, by decreasing adverse GI effects related to clopidogrel, might decrease patients' discontinuation of clopidogrel. In patients in whom there is a clear indication for PPI therapy, some clinicians may choose to use a PPI other than omeprazole.

6.1.2. Clopidogrel Genetic Testing: Recommendations

CLASS IIb

1. Genetic testing might be considered to identify whether a patient at high risk for poor clinical outcomes is predisposed to inadequate platelet inhibition with clopidogrel (829). *(Level of Evidence: C)*
2. When a patient predisposed to inadequate platelet inhibition with clopidogrel is identified by genetic testing, treatment with an alternate $P2Y_{12}$ inhibitor (e.g., prasugrel or ticagrelor) might be considered (829). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. The routine clinical use of genetic testing to screen patients treated with clopidogrel who are undergoing PCI is not recommended (829). *(Level of Evidence: C)*

On March 12, 2010, the FDA approved a new label for clopidogrel with a "boxed warning" about the diminished effectiveness of clopidogrel in patients with impaired ability to convert the drug into its active metabolite (829). Patients with decreased *CYP2C19* function because of genetic polymorphisms metabolize clopidogrel poorly and have higher rates of cardiovascular events after ACS and PCI than patients with normal *CYP2C19* function. The warning also notes that tests are available to identify patients with genetic polymorphisms and that alternative treatment strategies should be considered for patients who are poor metabolizers. The clopidogrel boxed warning leaves the issue of whether to perform *CYP2C19* testing up to the individual physician. It does not specifically require genetic testing or other changes in evaluation or treatment and does not imply that there are solid evidence-based reasons for such actions. Rather, it serves to inform clinicians of genetic variations in response to clopidogrel and to emphasize that clinicians should use this knowledge to make decisions about how to treat individual patients. At the present time, the evidence base is insufficient to recommend routine genetic testing in patients undergoing PCI. There may be a potential role for genetic testing for patients undergoing elective high-risk PCI procedures (e.g., unprotected left main, bifurcating left main, or last patent coronary artery).

6.1.3. Platelet Function Testing: Recommendations

CLASS IIb

1. Platelet function testing may be considered in patients at high risk for poor clinical outcomes (829). *(Level of Evidence: C)*
2. In patients treated with clopidogrel with high platelet reactivity, alternative agents, such as prasugrel or ticagrelor, might be considered (829). *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. The routine clinical use of platelet function testing to screen patients treated with clopidogrel who are undergoing PCI is not recommended (829). *(Level of Evidence: C)*

Platelet function testing to tailor antiplatelet therapy has received considerable interest. The GRAVITAS (Gauging Responsiveness With A VerifyNow Assay-Impact On Thrombosis And Safety) trial and several other ongoing trials test the concept that tailoring antiplatelet therapy based on platelet responsiveness assessed in an ex vivo $P2Y_{12}$ assay will improve cardiovascular outcomes (830). In GRAVITAS, treatment with high-dose clopidogrel for 6 months in patients with high platelet reactivity on standard-dose

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

clopidogrel was not beneficial. At the present time, the evidence base is insufficient to recommend routine platelet function testing. The results of 2 ongoing trials (DANTE [Dual Antiplatelet Therapy Tailored on the Extent of Platelet Inhibition] and ARCTIC [Double Randomization of a Monitoring Adjusted Antiplatelet Treatment Versus a Common Antiplatelet Treatment for DES Implantation, and Interruption Versus Continuation of Double Antiplate-let Therapy, One Year After Stenting]) will provide further information on the issue (www.clinicaltrials.gov).

6.2. Stent Thrombosis

The majority of stent thrombosis occurs early (0 to 30 days after PCI). In broad clinical practice, the expected rate of early stent thrombosis is <1%, and beyond 30 days it is 0.2% to 0.6% per year (210, 831). Acute stent thrombosis often presents as STEMI, and emergency revascularization is indicated. Acute stent thrombosis is associated with mortality rates of 20% to 45% (832). Survivors are also at risk of recurrent stent thrombosis (833).

Mechanical and pharmacological factors are the most frequent cause of acute stent thrombosis. After the usual measures to restore flow in the infarct-related artery, it is important to consider the etiology of stent thrombosis as it pertains to further therapy and avoidance of recurrence. IVUS may identify factors such as an undersized stent, incomplete stent apposition, residual stenosis, or dissection and can guide subsequent treatment. The most common cause of acute stent thrombosis is nonadherence to DAPT; however, resistance to aspirin or thienopyridines and pro-thrombotic states such as congenital or acquired thrombophilic states (malignancy) are additional risk factors (834, 835).

Given the poor prognosis of stent thrombosis and the uncertainties surrounding treatment, the importance of prevention must be emphasized. This includes ensuring compliance with DAPT and adequate stent sizing and expansion (836).

6.3. Restenosis: Recommendations

CLASS I

1. Patients who develop clinical restenosis after balloon angioplasty should be treated with BMS or DES if anatomic factors are appropriate and if the patient is able to comply with and tolerate DAPT (837). *(Level of Evidence: B)*
2. Patients who develop clinical restenosis after BMS should be treated with DES if anatomic factors are appropriate and the patient is able to comply with and tolerate DAPT (838–840). *(Level of Evidence: A)*

CLASS IIa

1. IVUS is reasonable to determine the mechanism of stent restenosis (495). *(Level of Evidence: C)*

CLASS IIb

1. Patients who develop clinical restenosis after DES may be considered for repeat PCI with balloon angioplasty, BMS, or DES containing the same drug or an alternative antiproliferative drug if anatomic factors are appropriate and the patient is able to comply with and tolerate DAPT (495). *(Level of Evidence: C)*

6.3.1. Background and Incidence. After balloon angioplasty, mechanisms contributing to restenosis include smooth muscle cell migration and proliferation, platelet deposition, thrombus formation, elastic recoil, and negative arterial remodeling. Stents block elastic recoil and negative remodeling, and the predominant mechanism for restenosis after stent implantation is neointimal hyperplasia. Restenosis rates vary, depending on whether angiographic restenosis (defined as >50% diameter stenosis at follow-up angiography) or clinical restenosis (symptomatic and requiring target-lesion revascularization or target-vessel revascularization) is measured, as well as on patient characteristics, coronary anatomy considerations, and device type (balloon angioplasty, BMS, or DES). The incidence of angiographic restenosis rates for uncomplicated lesions treated in RCTs ranges from 32% to 42% after balloon angioplasty (463, 464) and from 16% to 32% after BMS (463, 464), and is generally <10% after DES (454, 841). Less than half of patients with angiographic restenosis present with symptomatic, clinically relevant restenosis at 1-year follow-up, and a pooled analysis of 6,186 patients from 6 trials of BMS showed target-lesion revascularization was performed in 12% and target-vessel revascularization in 14% at 1 year (842, 843). Patients with clinical restenosis typically present with recurrent exertional angina, but 5% to 10% of patients present with acute MI and 25% with UA (844, 845).

Factors associated with an increased risk of restenosis in various models include clinical setting (STEMI, ACS, daily angina), patient characteristics (diabetes, age <55 to 60 years, prior PCI, male sex, multivessel CAD), lesion location (unprotected left main, SVG), and procedural characteristics (minimum stent diameter ≤2.5 mm, total stent length ≥40 mm) (778, 846).

PCI strategies for treating restenosis after balloon angioplasty, BMS, and DES are reviewed in the following sections. In addition to repeat PCI, intensified medical therapy or CABG are often also reasonable strategies, dependent on initial treatment (e.g., balloon

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

angioplasty, BMS), pattern of restenosis, likelihood of recurrent restenosis, ability to intensify medical therapy, suitability for CABG, and patient preference. Repeat PCI with BMS or DES is not appropriate if the patient is not able to comply with and tolerate DAPT.

6.3.2. Restenosis After Balloon Angioplasty. For clinical restenosis after balloon angioplasty, stent implantation is superior to repeat balloon angioplasty or atheroablation devices. The REST (REstenosis STent) study showed that target-lesion revascularization rates were 10% for stent-treated patients and 27% for balloon-treated patients (p=0.001) (837).

6.3.3. Restenosis After BMS. In-stent restenosis is classified according to these angiographic characteristics: Pattern I includes focal lesions $\leq$10 mm in length; Pattern II is in-stent restenosis >10 mm within the stent; Pattern III includes in-stent restenosis >10 mm extending outside the stent; and Pattern IV is totally occluded in-stent restenosis (847). Treatment of in-stent restenosis with balloon angioplasty, repeat BMS, or atheroablation devices for Patterns I to IV resulted in 1-year target-lesion revascularization rates of 19%, 35%, 50%, and 83%, respectively. For clinical restenosis after BMS, repeat stenting with DES is preferred. Studies have demonstrated lower recurrent restenosis rates with DES compared with BMS or vascular brachytherapy (495, 838–840).

6.3.4. Restenosis After DES. Clinical restenosis after placement of DES is becoming increasingly common due to the large numbers of patients who have been treated with DES. The predominant angiographic pattern for DES in-stent restenosis is focal ($\leq$10 mm in length). Several biologic, mechanical, and technical factors may contribute to DES in-stent restenosis, including drug resistance, hypersensitivity, stent underexpansion, stent strut fracture, nonuniform stent strut coverage, gap in stent coverage, and residual uncovered atherosclerotic lesion. IVUS might be considered to determine the cause for in-stent restenosis and help guide treatment strategy. Interventionists may treat focal DES restenosis with balloon angioplasty and treat nonfocal DES restenosis with BMS, CABG, or repeat DES with the same or an alternative antiproliferative drug (848, 849). Small, observational cohort studies have demonstrated angiographic restenosis rates of 25% to 30% with repeat DES either with the same or an alternative drug (495, 849, 850). There are no RCTs, and the most appropriate treatment of restenosis of DES remains unknown.

6.4. Clinical Follow-Up

At the time of discharge, patients are instructed to contact their physician or seek immediate medical attention if symptoms recur. Most physicians will give the patient instructions on return to work and timing of return to full activities. The importance of strict compliance with aspirin and $P2Y_{12}$ inhibitor therapy is ideally emphasized to the patient at the time of discharge and during follow-up visits.

Secondary prevention measures after PCI are an essential part of long-term therapy, reducing both future morbidity and mortality associated with CAD, and are discussed in Section 6.5. A follow-up visit after PCI is usually scheduled to assess the patient's clinical status, the patient's compliance with secondary prevention therapies, and the success of secondary prevention measures (e.g., blood pressure control, low-density lipoprotein levels, smoking cessation). Routine, periodic stress testing of asymptomatic patients is not considered part of standard patient follow-up.

6.4.1. Exercise Testing: Recommendations

CLASS IIa

1. In patients entering a formal cardiac rehabilitation program after PCI, treadmill exercise testing is reasonable. *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. Routine periodic stress testing of asymptomatic patients after PCI without specific clinical indications should not be performed (795). *(Level of Evidence: C)*

Treadmill exercise testing before cardiac rehabilitation provides information about peak exercise capacity and heart rate, helping to stratify patients for the level of supervision during training, and seems reasonable for this purpose (851); nuclear imaging to assess ischemia in this context usually adds little.

The role of exercise testing to evaluate restenosis is much less certain. Although the presence of symptoms may not be a reliable means of detecting restenosis, there is no evidence that the detection of silent restenosis leads to improved outcome (852, 853). Routine testing of all patients after PCI will also lead to many false-positive tests, particularly in the era of DES. As restenosis rates decline from 30% to 10%, the false-positive rate of stress imaging increases from 37% to 77% (854). A recent analysis of a national health insurance claims database and accompanying editorial find that stress testing after PCI is likely overused and rarely leads to repeat revascularization (855, 856). In summary, there is no proven benefit or indication for routine periodic stress testing in patients after PCI, and, thus, it is not indicated (8, 851). In cases in which there is a clear clinical indication for stress testing in a patient after PCI, exercise ECG alone is an insensitive predictor of restenosis (857, 858); therefore, stress

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

imaging is the preferred stress test (8). In cases of recurrent angina after PCI in which the pretest likelihood of restenosis is high and repeat revascularization based on symptoms is likely indicated, most practitioners will proceed directly to cardiac catheterization rather than first obtain stress imaging.

6.4.2. Activity and Return to Work. The timing of return to physical activity depends on the presenting condition as well as previous functional status. For STEMI, for example, daily walking is encouraged immediately, and driving can begin within 1 week after uncomplicated MI if allowed by local motor vehicle laws (859). Sexual activity usually can be resumed within days, provided exercise tolerance is adequate, normally assessed by the ability to climb a flight of stairs (859). Similar recommendations have been issued for UA/NSTEMI (860). Patients with UA who have undergone successful revascularization and are otherwise doing well may return to physical activity on an accelerated schedule, usually within a few days (860).

Return to work is more complex. Return to work rates after MI range from 63% to 94% and are confounded by factors such as job satisfaction, financial stability, and company policies (861). The physical demands and degree of stress of a particular job require that recommendations be individualized. In the PAMI-2 (Primary Angioplasty in Myocardial Infarction) trial, patients were encouraged to return to work 2 weeks after primary PCI for STEMI, and no adverse events were reported (862). In the RITA (Randomized Intervention Treatment of Angina) trial, revascularization with PCI led to earlier return to work compared with CABG, and subsequent employment rates were associated with relief of angina (105). Many practitioners use graded exercise treadmill testing to determine the safety of activity and return to work by measuring the metabolic equivalent of task (MET) level achieved and comparing that level to energy levels required to perform different activities (863).

6.4.3. Cardiac Rehabilitation: Recommendation

CLASS I

1. Medically supervised exercise programs (cardiac rehabilitation) should be recommended to patients after PCI, particularly for moderate- to high-risk patients for whom supervised exercise training is warranted (796–804). *(Level of Evidence: A)*

Participation in cardiac rehabilitation is associated with significant reductions in all-cause mortality (OR: 0.80, 95% CI: 0.68 to 0.93) and cardiac mortality (796, 797). Reports from community-based surveys, which in general enroll older and higher-risk patients than clinical trials, have confirmed that participation in comprehensive rehabilitation is independently associated with a reduction in recurrent MI and reduced mortality (799). Cardiac rehabilitation is also associated with improvements in exercise tolerance, cardiac symptoms, lipid levels, cigarette smoking cessation rates (in conjunction with a smoking cessation program), stress levels, improved medical regimen compliance, and improved psychosocial well-being (800). Cardiac rehabilitation is cost-effective as well (864). Physician referral may be the most powerful predictor of patient participation in a cardiac rehabilitation program (865).

6.5. Secondary Prevention

The treatment of the patient does not end with PCI; secondary prevention measures are a critical component of patient management. Important secondary prevention measures were presented in detail in the "2006 AHA/ACC Guidelines for Secondary Prevention for Patients With Coronary and Other Atherosclerotic Vascular Disease" (562) and have recently been updated in the "AHA/ACCF Secondary Prevention and Risk Reduction Therapy for Patients With Coronary and Other Atherosclerotic Vascular Disease: 2011 Update" (805). The reader is referred to this document for detailed discussions of secondary prevention. Among the important recommendations are the following:

- Lipid management with lifestyle modification *(Class I; Level of Evidence: B)* (805–807) and statin therapy are recommended. *(Level of Evidence: A)* (344, 806, 808–810, 810a) An adequate statin dose should be employed which reduces low-density lipoprotein cholesterol to <100 mg/dL AND achieves at least a 30% lowering of low-density lipoprotein cholesterol. *(Class I; Level of Evidence: C)* (806–810, 810a) It is reasonable to treat patients with statin therapy which lowers low-density lipoprotein cholesterol to <70 mg/dL in very high-risk* patients. *(Class IIa; Level of Evidence: C)* (345,808–810,810a,811,812) Patients who have triglycerides ≥200 mg/dL should be treated with statins to lower non-high-density lipoprotein cholesterol to <130 mg/dL. *(Class I; Level of Evidence: B)* (344, 809, 810, 866) In patients who are very high risk* and have triglycerides ≥200 mg/dL, a non-high-density lipoprotein cholesterol goal of <100 mg/dL is reasonable. *(Class IIa; Level of Evidence: C)* (344, 809, 810, 866).

*Presence of established cardiovascular disease plus 1) multiple major risk factors (especially diabetes), 2) severe and poorly controlled risk factors (especially continued cigarette smoking), 3) multiple risk factors of the metabolic syndrome (especially high triglycerides ≥200 mg/dL plus non-high-density lipoprotein cholesterol ≥130 mg/dL with low high-density lipoprotein cholesterol [40 mg/dL]), and 4) acute coronary syndromes.

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

- Blood pressure control with lifestyle modification *(Class I; Level of Evidence: B)* (813–817) and pharmacotherapy *(Class I; Level of Evidence: A)* (805, 813, 818, 819), with the goal of blood pressure <140/90 mm Hg.
- Diabetes management (e.g., lifestyle modification and pharmacotherapy), coordinated with the patient's primary care physician and/or endocrinologist. *(Class I; Level of Evidence: C)* (805)
- Advising patients on the need for complete smoking cessation. *(Class I; Level of Evidence: A)* (805, 820–823)

7. QUALITY AND PERFORMANCE CONSIDERATIONS

7.1. Quality and Performance: Recommendations

CLASS I

1. Every PCI program should operate a quality-improvement program that routinely 1) reviews quality and outcomes of the entire program; 2) reviews results of individual operators; 3) includes risk adjustment; 4) provides peer review of difficult or complicated cases; and 5) performs random case reviews. *(Level of Evidence: C)*
2. Every PCI program should participate in a regional or national PCI registry for the purpose of benchmarking its outcomes against current national norms. *(Level of Evidence: C)*

PCI quality and performance considerations are defined by attributes related to structure, processes, and risk-adjusted outcomes. Structural attributes include elements such as equipment, supplies, staffing, institutional and operator-level volumes, and the availability of electronic medical records. Processes include strategies for the appropriate patient, protocols for pre- and postprocedural care, appropriate procedural execution and management of complications, and participation in databases and registries for benchmarking performance of the program and individual operator. Risk-adjusted outcomes are the end result of these structures and processes of care, and when available are more reliable measures of quality than the institutional and individual operator volumes discussed in Section 7.4.

PCI process and outcomes assessments can be used for internal quality-improvement efforts and public reporting. Public reporting of institutional risk-adjusted outcomes is becoming more common. Although operator-level outcomes can be assessed and risk adjusted, the results are much less reliable due to lack of statistical power resulting from lower volumes. Any public reporting must use statistical methods that meet the high criteria established by the AHA Work Group (867).

7.2. Training

The cognitive knowledge and technical skill required to perform PCI continue to grow. Details on the training required for interventional cardiology are found in the most recent ACCF Core Cardiology Training Statement (868).

7.3. Certification and Maintenance of Certification: Recommendation

CLASS IIa

1. It is reasonable for all physicians who perform PCI to participate in the American Board of Internal Medicine interventional cardiology board certification and maintenance of certification program. *(Level of Evidence: C)*

The American Board of Internal Medicine established interventional cardiology board certification in 1999 as an "added qualification" to the cardiovascular disease board certification. Since 1990 all certificates from the American Board of Internal Medicine are time limited for a 10-year period and require all diplomats to participate in maintenance of certification to maintain their board-certified status. Maintenance of certification in interventional cardiology requires physicians to document a minimum of 150 interventional cases over the 2 years before expiration of the current certification, complete self-assessment modules of their medical knowledge, participate in practice-based quality-improvement activities, and pass a secure, knowledge-based examination (869–871). For those who cannot meet the case volume requirement, an alternative option is to submit a log of 25 consecutive cases including patient characteristics and procedural outcomes. The maintenance of certification process is likely to change, as the American Board of Internal Medicine intends to evolve maintenance of certification from an episodic event that occurs once every 10 years to a more continuous process of continuous professional development.

7.4. Operator and Institutional Competency and Volume: Recommendations

CLASS I

1. Elective/urgent PCI should be performed by operators with an acceptable annual volume (≥75 procedures) at high-volume centers (>400 procedures) with on-site cardiac surgery (872, 873). *(Level of Evidence: C)*

Catheterization and Cardiovascular Interventions DOI 10.1002/ccd.
Published on behalf of The Society for Cardiovascular Angiography and Interventions (SCAI).

2. Elective/urgent PCI should be performed by operators and institutions whose current risk-adjusted outcomes statistics are comparable to those reported in contemporary national data registries. *(Level of Evidence: C)*
3. Primary PCI for STEMI should be performed by experienced operators who perform more than 75 elective PCI procedures per year and, ideally, at least 11 PCI procedures for STEMI per year. Ideally, these procedures should be performed in institutions that perform more than 400 elective PCIs per year and more than 36 primary PCI procedures for STEMI per year (872, 874–877). *(Level of Evidence: C)*

CLASS IIa

1. It is reasonable that operators with acceptable volume (≥75 PCI procedures per year) perform elective/urgent PCI at low-volume centers (200 to 400 PCI procedures per year) with on-site cardiac surgery (872). *(Level of Evidence: C)*
2. It is reasonable that low-volume operators (<75 PCI procedures per year) perform elective/urgent PCI at high-volume centers (>400 PCI procedures per year) with on-site cardiac surgery. Ideally, operators with an annual procedure volume of fewer than 75 procedures per year should only work at institutions with an activity level of more than 600 procedures per year. Operators who perform fewer than 75 procedures per year should develop a defined mentoring relationship with a highly experienced operator who has an annual procedural volume of at least 150 procedures per year. *(Level of Evidence: C)*

CLASS IIb

1. The benefit of primary PCI for STEMI patients eligible for fibrinolysis when performed by an operator who performs fewer than 75 procedures per year (<11 PCIs for STEMI per year) is not well established. *(Level of Evidence: C)*

CLASS III: NO BENEFIT

1. It is not recommended that elective/urgent PCI be performed by low-volume operators (<75 procedures per year) at low-volume centers (200 to 400 procedures per year) with or without on-site cardiac surgery. An institution with a volume of fewer than 200 procedures per year, unless in a region that is underserved because of geography, should carefully consider whether it should continue to offer this service (872). *(Level of Evidence: C)*

Older observational evidence supported a volume-outcome relationship in PCI at both the institutional and operator level (873). However, this relationship is complicated and may be inconsistent across low-volume institutions or operators. More recent data on primary PCI suggest that operator experience may modify the volume-outcome relationship at the institutional level (876, 878). Risk-adjusted outcomes remain preferable to institutional and individual operator volumes as quality measures.

Operator and hospital volume recommendations have been carried over from the 2005 PCI guideline. However, the writing committee recognizes that these volume recommendations are controversial. In addition, after extensive review of all relevant data, the writing committee believes that the LOE in support of all the above recommendations is best categorized as LOE C rather than LOE B as it has been in prior guidelines for some recommendations. We encourage the ACCF/AHA/ACP Clinical Competence and Training writing group for PCI and other expert writing groups to review this issue so that new recommendations can be considered by the next PCI guideline writing committee.

7.5. Participation in ACC NCDR or National Quality Database

Assessment of PCI quality and outcomes is important both at the level of the entire program and at the level of the individual physician. This requires collection of clinical and procedural data for PCI that allows regular comparison of risk-adjusted outcomes and complications with national benchmarks. The ACC NCDR CathPCI Registry is an example of a national registry to fulfill the goals of assessing and benchmarking quality and outcomes.

8. FUTURE CHALLENGES

Although this latest guideline reflects significant advancements in the field of PCI, there remain future challenges to the formulation and updating of guidelines for PCI. The proliferation of studies comparing the many newer drugs and devices with older therapies (or other newer therapies), often using different or novel study endpoints, endpoint definitions, and noninferiority designs, pose increasing challenges to objectively evaluating newer therapies and generating recommendations for their use. Numerous potential advances in the field of PCI, including intracoronary stem cell infusions for chronic and acute ischemic heart disease, designer drugs, novel intracoronary imaging technologies such as optical coherence tomography and virtual histology, new stent composition and designs (e.g., drug-eluting, biodegradable, bifurcation), and drug-eluting balloons were considered for formal evaluation by the current writing committee, but it was thought that

ID: kandasamy.d | Black Lining: [ON] | Time: 12:19 | Path: N:/3b2/CCD#/Vol00000/110478/APPFile/JW-CCD#110478

there were insufficient data at present to formulate any formal recommendations on these topics. These and other emerging technologies and treatments will need to be addressed in future PCI guidelines.

Finally, with this proliferation of new technology, the amount of data generated in the evaluation of these potential therapeutic advances will grow dramatically, adding significant challenges to future guideline generations. Of note, the Web site www.clinicaltrials.gov currently lists several hundred PCI-related clinical trials.
