HARTFORD CT 06134

May, 2002

This work was supported in part by Contract N01-CN-67005 between the National Cancer Institute and the Connecticut Department of Public Health.

Requests for further information, and questions about this report, should be directed to Anthony P. Polednak, Ph.D., at the Connecticut Tumor Registry (telephone 860-509-7163)

## **Table of Contents**

Introduction and methods	3
All invasive cancers, males	9
All invasive cancers, females	13
Colon-rectum, males	17
Colon-rectum, females	21
Lung, males	25
Lung, females	29
Prostate, males	33
Breast, females	37
Melanoma of skin, males	41
Melanoma of skin, females	45
Uterine cervix, females	49
Appendix, maps	53

## **Introduction and Methods**

The population-based Connecticut Tumor Registry (CTR) frequently receives inquiries concerning whether or not the number of cancers in a given town, or group of towns, is unusual in comparison with other parts of the state. This monograph is intended to provide some data that should be useful in answering these questions.

This monograph presents data for incident cancers diagnosed among Connecticut residents during 1995-1999. Other recent reports from the CTR have included data on selected types of incident cancers diagnosed in 1997, 1998 and 1999. Incidence data for a single year of diagnosis must be used with caution, because numbers of cancers are small and fluctuate randomly from year to year. A previous monograph included data on selected major cancer types (sites) by town for 1990-94. Surveillance of cancer incidence by town is an ongoing effort of the CTR. Future analyses will include data for diagnoses in the years 2000 and 2001, which will allow comparison with findings reported for cancers diagnosed in 1989-91 (Polednak and Flannery, 1995) and 1990-94 (Polednak, 1998), so that any suggested trends in cancer incidence rates by town can be determined.

As with previous CTR monographs, this report excludes "in situ" (non-invasive) cancers, with the sole exception of bladder tumors. Because of well-known problems in distinguishing in situ from invasive bladder tumors, the National Cancer Institute includes both in situ and invasive bladder cancers when reporting data on all invasive cancers combined.

Data for all invasive cancers combined are most frequently requested, and are provided in this report, along with data for the most common cancers (breast, prostate, lung and colorectal). With 169 towns in Connecticut, numbers for many types of cancer are small for many towns. However, two other cancer sites were also included because of special interest. Melanoma of the skin was included because incidence rates have previously been shown to differ by town of residence in Connecticut. Invasive cervical cancer is of special interest because of the important role of screening in preventing these cancers.

Numbers presented in this report are cancers, not persons with cancer. An individual can be diagnosed with two different types of cancer at the same time or during a given time period.

### **Calculation and Presentation of Standardized Incidence Ratios (SIRs)**

For each town, the observed number of cancers is compared with the number expected for each town if statewide incidence rates prevailed. The ratio of the observed to the expected number of cancers for each town is the "standardized incidence ratio" or SIR.

In calculating SIRs, statewide incidence rates were first obtained for 1995-1999 for each specific type of cancer for each sex by age group, using state population estimates by age and sex for 1995-99 (reported by the U.S. Bureau of the Census). These rates were multiplied by the male or female populations in

each age group in the town from the 2000 Census; the sum of these products, across all the age groups, is the expected number of cancers, as shown in the tables in this report. Age was in five-year intervals from 0-4 to 80-84 years, with age 85 years or older as the last age interval. Accurate data on populations by age and sex for each town were available only for the year 2000. Using statewide incidence rates for 1995-99 based on statewide population estimates for 1995-99, while using population estimates for each town for 2000, introduces a small error in the calculation of SIRs for 1995-99 by town. Within this limitation, an SIR of 1.00 can be interpreted as indicating that the number of cancers observed for a town was approximately equal to the number expected for the town's population (in 2000) on the basis of statewide cancer incidence rates for 1995-99.

The analysis of SIRs by geographic area is a tool in cancer surveillance. The use of SIRs, however, does not permit identification of specific age subgroups that may be involved in any finding of elevated or reduced SIRs in specific towns. This would require examination of age-specific incidence rates, which for many towns involve small numbers of cancers and large statistical uncertainty.

#### **Interpretation of SIRs**

Apparent geographic variation in SIRs must be interpreted with caution. As with other cancer registries, the only address reported to the CTR for some persons is a post-office box rather than the actual residence. A town with a post office has an unusually high SIR while an adjacent town without a post office has an unusually low SIR. For example, a large proportion of records coded with Voluntown as the town of residence have a post office box as the only address in the CTR; some of these patients are residents of the adjacent town of Griswold, which has no post office. Several other small towns do not have a post office. For example, some residents of the town of Warren have mail delivery while others do not; the mailing address for some residents of Warren is Cornwall Bridge (Town of Cornwall). Therefore, cancer rates may appear unusually high or low, due to errors in assigning town of residence. This problem has also been reported for the New York State cancer registry (Nasca et al., 1980). In Connecticut, due to problems with assigning residence to the towns of North Canaan (which includes a Village named Canaan) and Canaan, data for these two towns were combined in all tables in this report.

An elevated SIR does not necessarily indicate a finding of public health significance. Elevated SIRs can occur due to inaccuracies in population estimates (by age and sex), as well as inaccuracies in assignment to town of residence, chance or random variation, and differences in the socioeconomic status of residents of different towns, rather than to any effects of living in a particular town. With regard to population estimates, the Bureau of the Census has indicated an error in assigning some residents to West Hartford vs. Hartford in the Year 2000 Census; corrected data have not been obtained.

Differences in cancer incidence rates by town may reflect the association between socioeconomic status and cancer rates

(Baquet et al., 1991). For some types of cancer, such as cancers of the uterine cervix and lung, incidence rates tend to be higher in the lower levels of socioeconomic status (usually defined by level of education or income). For a few types of cancer, such as breast and testis, incidence rates tend to be higher in higher socioeconomic status groups.

The association between higher socioeconomic status and risk of breast cancer is due at least in part to differences in fertility and reproductive history, which are major known risk factors for breast cancer. Rates for certain other cancers are not associated with socioeconomic status but with population density (that is, the number of people per square mile). Thus, differences in SIRs among towns may reflect differences in these characteristics of the residents, rather than differences in the general environment.

In the 1990 Census, median household income varied from around \$80,000-104,000 in several towns in the southwestern corner of the state (near New York City) to less than \$30,000 in New London, Norwich, Putnam and Windham, and less than \$25,000 in Bridgeport and Hartford. Other higher-income regions include several suburban towns near the cities of Hartford and New Haven. The proportion of persons with incomes below the federal poverty threshold, which takes into account the number of persons in a household, was highest in Hartford (27.5%) and New Haven (21.3%) and greater than 10% for several other towns (Bridgeport, Mansfield, New Britain, New London, Norwich, Putnam, Sprague, Waterbury and Windham), according to 1990 census reports.

Because the risk of breast cancer is increased among women of higher socioeconomic status, towns with larger proportions of such women will have relatively high SIRs prior to adjustment based on socioeconomic indicators for each town but not after adjustment (Polednak, 1998). Towns with higher levels of income will tend to have lower prevalences of cigarette smokers, and lower rates for lung cancer and other cancers related to smoking.

The distribution of racial-ethnic groups also differs by county and town. The proportions of black and Hispanic persons in the population in the 1990 Census were highest in the largest cities (Bridgeport, Hartford, New Haven and Waterbury). Total cancer incidence rates are higher for blacks (and especially black males) and lower for Hispanics, relative to rates for all groups combined or for non-Hispanic whites. Although these racial-ethnic differences are due largely to differences in socioeconomic status, explanations for some racial-ethnic differences for specific cancer sites may be more complex.

This report does not attempt to provide separate SIRs for blacks or for Hispanics, because of the small population sizes and the small numbers of cancers in many towns. Also, there are problems with identifying Hispanics in the Registry. However, differences in racial-ethnic composition among the towns and counties should be considered in interpreting the SIRs.

Certain cancers, such as breast and prostate, are often detected by screening tests, including mammography and clinical breast examination for breast cancer, and both digital rectal examination and prostate-specific antigen (PSA) testing for prostate. Because rates of cancer screening vary geographically,

the distribution of detected cancers over space and time may be affected.

A long time period ("latent period" or "latency") is generally involved between exposure to a cancer-causing agent ("carcinogen") and diagnosis of cancer related to that exposure. An example is the long time interval usually involved between initiation of tobacco use and the diagnosis of lung cancer. The mobility of the population reduces the possibility that any exposures occurring during recent residence in a given town are related to the development of cancer. Rather, exposures occurring many years earlier, during residence in another geographic area, may be important.

Cancers associated with general environmental exposures such as ambient air and water pollution may be expected to be elevated for both males and females in geographic areas with higher levels of these agents. For other risk factors, such as diet and smoking habits, gender differences in the prevalence of the risk factor may exist within a given region but adequate data on the prevalence of cancer risk factors within Connecticut are not available, so that interpretation of SIRs is difficult. However, geographic patterns in SIRs could suggest the need to consider special surveys of risk factors in specific regions.

High SIRs for lung cancer in certain geographic areas could suggest the need for intensified smoking prevention and cessation programs. High SIRs for skin melanomas in specific towns could indicate the need for public education regarding the dangers of excessive sun exposure.

#### **Highlights of the Data**

##### **All Invasive Cancers Combined**

For males, SIRs were greater than 1.00 for some of the largest towns (Bridgeport, East Hartford, Hartford and New Haven), with large proportions of lower-income persons and blacks. For females, high SIRs were evident for fewer towns than males; included were New Haven and New London.

Problems with post-office box addresses also should be kept in mind, for smaller towns. In interpreting maps (see Appendix), reference should be made to the tables, which indicate towns for which SIRs are based on small numbers (often, less than 10 cancers).

##### **Colorectal Cancer**

As in previous reports from the CTR, there was little geographic variation in incidence rates for colorectal cancer at the town level. Elevated SIRs were found for New Haven and Waterbury in males, and for Bridgeport and New Haven in females. The causes of colorectal cancer are poorly understood, although dietary factors are probably involved. Screening can reduce the incidence of invasive cancers, through detection and surgical removal of pre-invasive lesions (polyps).

##### **Lung Cancer**

For males, towns with elevated SIRs included several with less-affluent populations (Bridgeport, East Hartford, Hartford, New Haven, Waterbury and Windham). Elevated SIRs were found for females in East Hartford, and also in Milford, West Haven and New London, but the numbers of cancers involved were smaller than for males and many SIRs were statistically unreliable. SIRs were elevated for females in certain towns in New London county, as

also reported previously (Polednak and Flannery, 1995; Polednak, 1998). Elevated SIRs could be due to chance, higher prevalence of smokers, and/or occupational factors; occupational exposures account for a small proportion of all lung cancers.

#### **Prostate Cancer**

Several towns in the Hartford area had SIRs that were higher than predicted, as noted in previous reports from the Registry. Another group of towns with relatively high SIRs was evident in the southeastern corner of the state (Fairfield County). Geographic variation must be interpreted with caution because the incidence of detected cancers is influenced by medical care, which affects the probability of detecting "latent" or clinically silent cancers. Detection of more cancers through increased screening of asymptomatic patients may lead to temporary increases in incidence rates (mainly for early-stage cancers).

#### **Breast Cancer**

SIRs were elevated for a several towns, widely scattered throughout the state, including Simsbury and certain other Hartford suburbs, and certain towns in Fairfield County with relatively high socioeconomic indicators in the U.S. census. These socioeconomic differences, and differences in screening rates, appear to explain the geographic differences in SIRs for breast cancer (Polednak, 1998). Geographic differences in breast cancer screening rates can affect the space-time distribution of reported cancers, because screening programs or special efforts in specific geographic areas usually leads to increases in the number of breast cancers detected.

#### **Melanoma of Skin**

Relatively high SIRs were found for certain affluent towns (Avon, Canton and West Hartford in males and Simsbury and Eastport in females) and for certain towns on the ocean shoreline (including Darien, Fairfield, Groton, Guilford, Madison, Old Lyme and Wilton in males, and Madison, Westport and Wilton in females) High SIRs are also found for some towns located near lakes. Several publications from the Registry have dealt with this issue (see References, listed below), and the suggestion that recreational exposure to the sun may be involved.

#### **Cervical Cancer**

Numbers of invasive cervical cancer were small for most towns, so that SIRs were tabulated but not mapped. Noteworthy were the high SIRs for Bridgeport, Hartford and New Haven. These towns include high-poverty areas, where risk factors for cervical cancer tend to be more prevalent and cancer screening less prevalent (Polednak et al., 1991).

#### **Conclusion**

Variation in standardized incidence ratios (SIRs) among the towns should be interpreted with caution. High or low SIRs may not be due to any effect of living in a particular town, especially in view of population mobility and the long latent periods involved for many cancers. In addition to random (statistical) variation, SIRs are subject to the effects of inaccuracies in assignment of place of residence as well as variation in cancer screening rates. Variation in the characteristic of the population, including the distribution of socioeconomic status and

racial-ethnic groups, must be considered in interpreting the SIRs by town. For melanoma of the skin, however, certain ocean shoreline towns have high SIRs (as previously reported). Even if the apparent variation in SIRs is largely explained by differences in socioeconomic status indicators among the towns, this information can be of practical importance. Towns with low socioeconomic indicators tend to have relatively high prevalence rates of cigarette smoking, and could be specially targeted for interventions aimed at prevention or cessation of smoking. More-affluent towns could be specially targeted in programs aimed at primary prevention of breast cancer, through modification of lifestyle factors. More-affluent towns, especially certain towns on the ocean shoreline, could benefit from programs aimed at reducing excess recreational exposure to the sun (especially at beaches).

#### **Disclaimer**

Persons using the data in this report are asked to include a disclaimer statement, preferably: "Certain data used in this [study, report, publication, document, etc.] were obtained from information in a monograph produced by the Connecticut Tumor Registry. The author(s) assume(s) full responsibility for the analysis and/or interpretation of these data."

## APPENDIX

### Codes Used for Cancer Sites

The types of cancer presented in this report were defined by codes in the database of the Connecticut Tumor Registry, which uses the International Classification of Diseases for Oncology (ICD-O, version 2) codes for topography (site), morphology (histology) and behavior (i.e., benign, uncertain, in situ, and malignant). Certain benign tumors are reported to the registry but were not included in this report; as noted earlier, in situ tumors were also excluded from this report, with the sole exception of in situ bladder tumors (which were included). Lymphomas are not coded to the site of occurrence, but are grouped together into separate categories (i.e., Hodgkin's disease and non-Hodgkin's lymphoma), which were not included in this report.

The ICD-O-2 site codes involved in this report were:

LUNG (TRACHEA, BRONCHUS, LUNG): C 339-349.

MELANOMA OF SKIN: C 440-449, Morphology 8720-8799.

PROSTATE: C 619.

FEMALE BREAST: Sex female and C 500-509.

COLON-RECTUM:

COLON: C 180-189

RECTUM, ANUS: C 199, 209-218

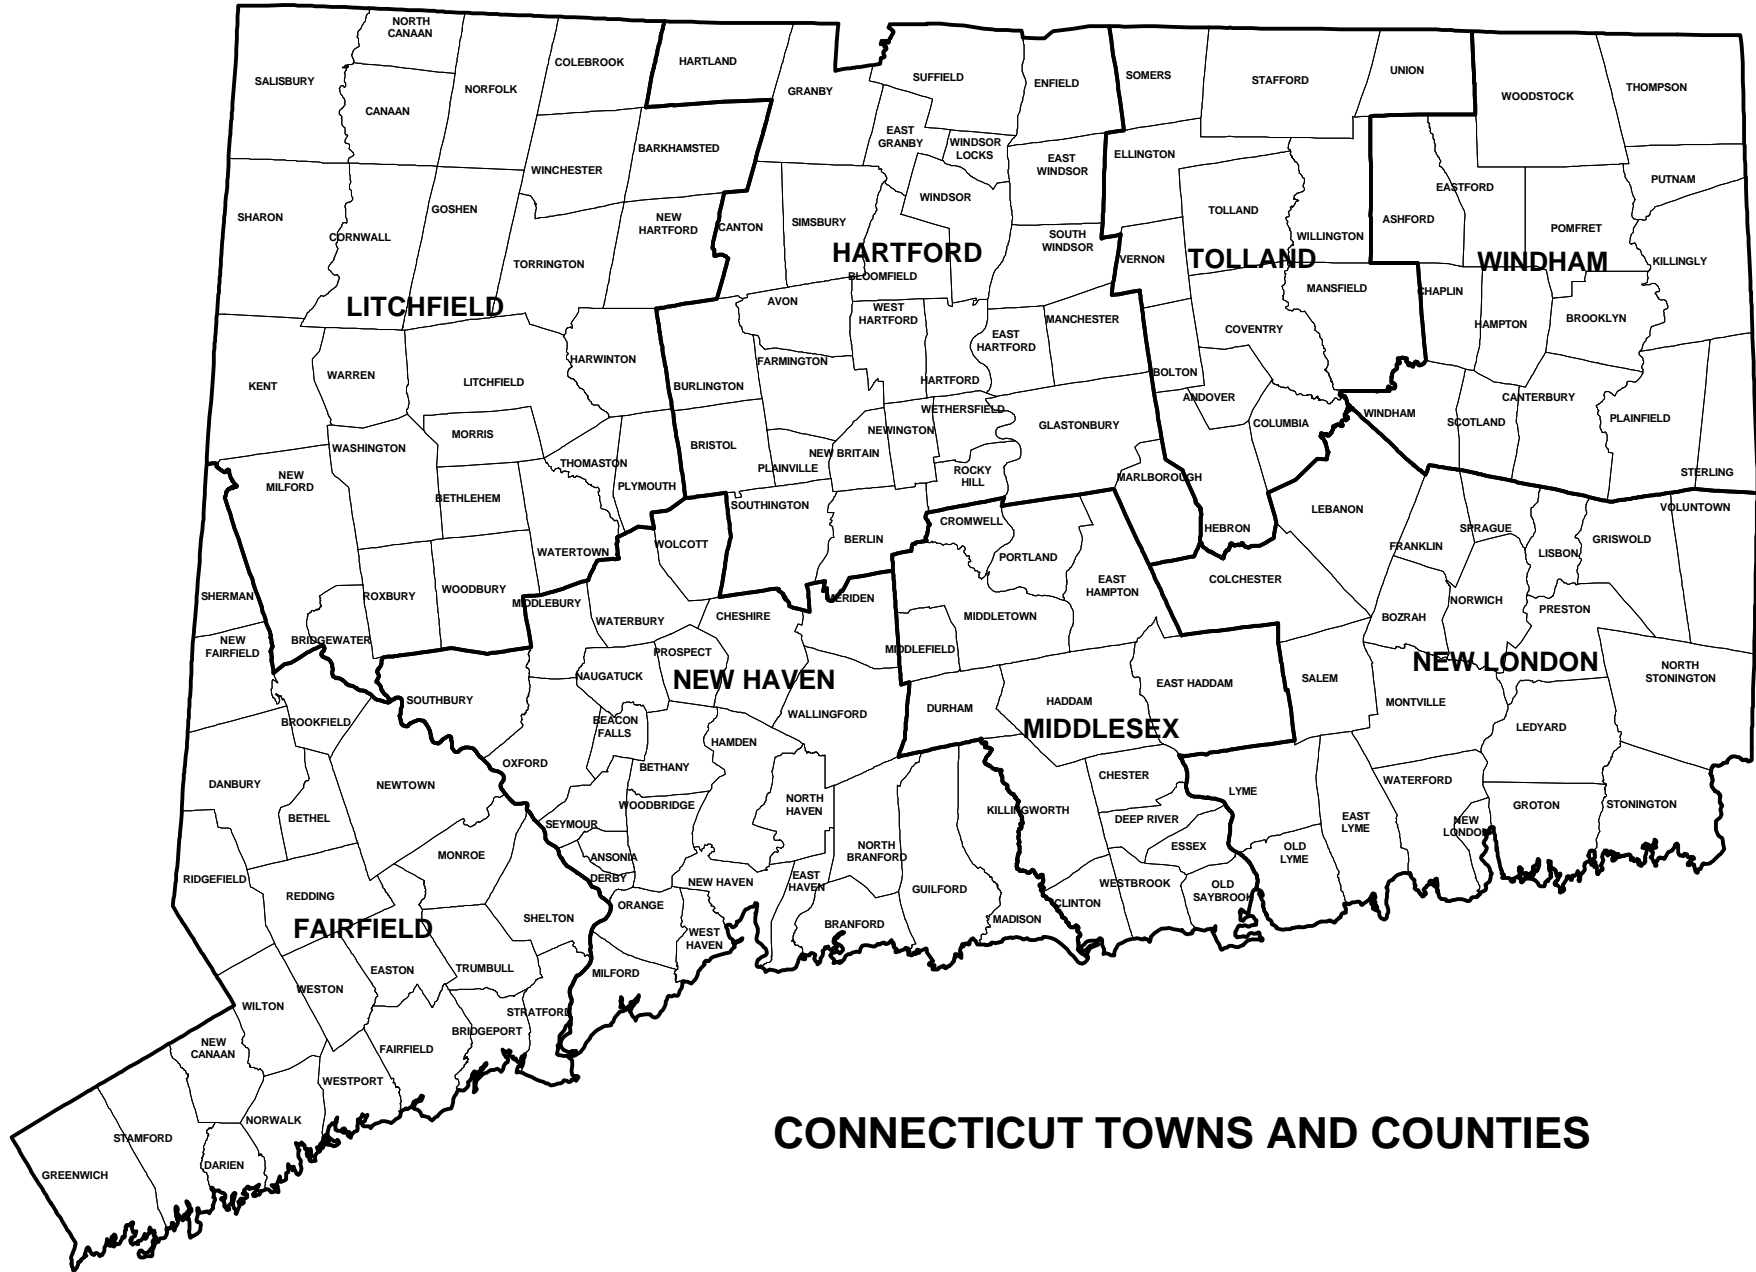

UTERINE CERVIX : C530-539

## MAPS

1. Boundaries and names of Connecticut towns and counties
2. SIRs for all invasive cancers, males
3. SIRs for all invasive cancers, females
4. SIRs for colorectal cancer, males
5. SIRs for colorectal cancer, females
6. SIRs for lung cancer, males
7. SIRs for lung cancer, females
8. SIRs for prostate cancer
9. SIRs for breast cancer, females
10. SIRs for melanoma of skin, males
11. SIRs for melanoma of skin, females

- Note:
1. An asterisk (star) on these maps indicates that the SIR was statistically significantly higher than 1.00, as indicated by the 95% confidence limits in the tables (that is, the lower confidence limit was greater than 1.00).
  2. Maps were prepared by Charles Nathan, Office of Policy, Planning and Evaluation, Connecticut Dept. of Public Health
